An event is like a message announcing that something important has occurred. The act of broadcasting the message is called *raising* the event. In Visual Basic .NET, you raise events with the **RaiseEvent** statement, as in the following example:

```
RaiseEvent AnEvent(EventNumber)
```

Events must be raised within the scope where they are declared. For example, a derived class cannot raise events inherited from a base class.

Event Senders

Any object capable of raising an event is an *event sender*, also known as an *event source*. Forms, controls, and user-defined objects are examples of event senders.

Event Handlers

Event handlers are procedures that are called when a corresponding event occurs. You can use any valid subroutine as an event handler. You cannot use a function as an event handler, however, because it cannot return a value to the event source.

Visual Basic uses a standard naming convention for event handlers that combines the name of the event sender, an underscore, and the name of the event. For example, the click event of a button named `button1` would be named `Sub button1_Click`.

> **Note** It is recommended that you use this naming convention when defining event handlers for your own events, but it is not required; you can use any valid subroutine name.

Associating Events with Event Handlers

Before an event handler becomes usable, you must first associate it with an event by using either the **Handles** or **AddHandler** statement.

The **WithEvents** statement and **Handles** clause provide a declarative way of specifying event handlers. Events raised by an object declared with **WithEvents** can be handled by any subroutine with a **Handles** clause that names this event. Although the **Handles** clause is the standard way of associating an event with an event handler, it is limited to associating events with event handlers at compile time.

The **AddHandler** and **RemoveHandler** statements are more flexible than the **Handles** clause. They allow you to dynamically connect and disconnect the events with one or more event handlers at run time, and they do not require you to declare object variables using **WithEvents**.

In some cases, such as with events associated with forms or controls, Visual Basic .NET automatically stubs out an empty event handler and associates it with an event. For example, when you double-click a command button on a form in design mode, Visual Basic .NET creates an empty event handler and a **WithEvents** variable for the command button, as in the following code:

```
Friend WithEvents Button1 As System.Windows.Forms.Button
Protected Sub Button1_Click(ByVal sender As System.Object, _
   ByVal e As System.EventArgs) Handles Button1.Click
End Sub
```

AddHandler and RemoveHandler | Writing Event Handlers | Handles | Addhandler Statement

Adding Events to a Class

You add events to a class by declaring them with the **Events** statement. The declaration includes the name of the event and the arguments it uses.

To add an event to a class

- In the Declarations section of the class module that defines the class, use the **Event** statement to declare the event with whatever arguments you want it to have. For example:

```
Public Event PercentDone(ByVal Percent As Single, _
   ByRef Cancel As Boolean)
```

Events cannot have return values, optional arguments, or **ParamArray** arguments.

Adding an event to a class specifies that an object of this class can raise a specific event. To cause an event to actually happen, you must use the **RaiseEvent** statement. You can use **Handles** keyword or **AddHandler** statement to associate the event with an event handler procedure. Events must be raised within the scope where they are declared. For example, a derived class cannot raise events inherited from a base class.

Writing Event Handlers

The way you construct an event handler depends on how you want to associate it with events. The standard way to create an event handler is to use the **Handles** keyword with the **WithEvents** keyword. Visual Basic .NET provides a second way to handle events: the **AddHandler** statement. **AddHandler** and **RemoveHandler** allow you to dynamically start and stop event handling for a specific event. You can use either approach, but you should not use both **WithEvents** and **AddHandler** with the same event.

Handling Events Using WithEvents

The **WithEvents** keyword allows you to create class or module-level object variables that can be used with the **Handles** clause in event handlers.

To handle events using WithEvents and the Handles clause

1. In the Declarations section of the module that will handle the event, use the **WithEvents** keyword to declare an object variable for the source of your events, as in the following example:

```
Public WithEvents ClassInst As Class1
```

2. In the Code editor, choose the **WithEvents** variable you just declared from the **Class Name** drop-down list on the left.
3. Choose the event you want to handle from the **Method Name** drop-down list on the right. The Code editor creates the empty event handler procedure with a **Handles** clause.

   Note This step is optional. You can create the event handler procedure manually as long as the procedure you create is a subroutine, has the correct argument list to match the event being handled, and has a **Handles** clause that specifies the event being handled.

4. Add event-handling code to the event handler procedure using the supplied arguments. The following code provides an example:

```
Public Sub ClassInst_AnEvent(ByVal EventNumber As System.Integer) _
      Handles ClassInst.AnEvent
   MessageBox.Show("Received event number: " & CStr(EventNumber))
End Sub
```

Handling Events Using AddHandler

You can use the **AddHandler** statement to dynamically connect events with event handler procedures.

To handle events using AddHandler

1. Declare an object variable of the class that is the source of the events you want to handle. Unlike a **WithEvents** variable, this can be a local variable in a procedure; for example:

```
Dim CI As New Class1()
```

2. Use the **AddHandler** statement to specify the name of the event sender, and the **AddressOf** statement to provide the name of your event handler; for example:

```
AddHandler CI.AnEvent, AddressOf EHandler
```

   Any procedure can serve as an event handler as long as it supports the correct arguments for the event being handled.

3. Add code to the event handler, as in the following example:

```
Public Sub EHandler(ByVal EventNumber As Integer)
   MessageBox.Show("Received event number " & CStr(EventNumber))
End Sub
```

Using RemoveHandler to Stop Handling Events

You can use the **RemoveHandler** statement to dynamically disconnect events from event handler procedures.

To stop handling events using RemoveHandler

1. Use the **RemoveHandler** statement to specify the name of the event sender, and the **AddressOf** statement to provide the name of your event handler. The syntax for **RemoveHandler** statements will always closely match the **AddHandler** statement used to start event handling; for example:

```
RemoveHandler CI.AnEvent, AddressOf EHandler
```

Handling Events Inherited from a Base Class

Derived classes — classes that inherit characteristics from a base class — can handle events raised by their base class using the **Handles MyBase** statement.

To handle events from a base class

- Declare an event handler in the derived class by adding a **Handles MyBase.<event name>** statement to the declaration line of your event handler procedure, where **event name** is the name of the event in the base class you are handling. For example:

```
Public Class Class1
   Public Event SE(ByVal i As Integer)
   ' Place methods and properties here.
End Class

Public Class Class2
   Inherits Class1
   Sub EventHandler(ByVal x As Integer) Handles MyBase.SE
   ' Place code to handle events from Class1 here.
   End Sub
End Class
```

See Also

Handles | Addhandler Statement | Events and Event Handlers | Delegates and the AddressOf Operator | AddHandler and RemoveHandler | Writing Event Handlers

WithEvents and the Handles Clause

The **WithEvents** statement and the **Handles** clause provide a declarative way of specifying event handlers. Events raised by an object declared with the **WithEvents** keyword can be handled by any procedure with a **Handles** statement for that event, as shown in the following example:

```
Dim WithEvents EClass As New EventClass() ' Declare a WithEvents variable.
Sub TestEvents()
   EClass.RaiseEvents()
End Sub
' Declare an event handler that handles multiple events.
Sub EClass_EventHandler() Handles Eclass.XEvent, Eclass.YEvent
   MsgBox("Received Event.")
End Sub

Class EventClass
   Public Event XEvent()
   Public Event YEvent()
   Sub RaiseEvents() 'Raises two events handled by EClass_EventHandler.
      RaiseEvent XEvent()
      RaiseEvent YEvent()
   End Sub
End Class
```

The **WithEvents** statement and the **Handles** clause are often the best choice for event handlers, because the declarative syntax they use makes event handling easier to code, read and debug. However, be aware of the following limitations on the use of **WithEvents** variables:

- You cannot use a **WithEvents** variable as a generic object variable. That is, you cannot declare it as **Object** — you must specify the class name when you declare the variable.
- You cannot use **WithEvents** to declaratively handle shared events, since they are not tied to an instance that can be assigned to a **WithEvents** variable.
- You cannot create arrays of **WithEvents** variables.
- **WithEvents** variables allow a single event handler to handle one or more kind of event, or one or more event handlers to handle the same kind of event.

See Also

AddHandler and RemoveHandler | Handles | WithEvents

AddHandler and RemoveHandler

The **AddHandler** statement is similar to the **Handles** clause in that both allow you to specify an event handler that will handle an event. However, **AddHandler** along with **RemoveHandler** provide greater flexibility than the **Handles** clause, allowing you to dynamically add, remove, and change the error handler associated with an event. And unlike **Handles**, **AddHandler** allows you to associate multiple event handlers with a single event.

AddHandler takes two arguments: the name of an event from an event sender such as a control, and an expression that evaluates to a delegate. You do not need to explicitly specify the delegate class when using **AddHandler**, since the **AddressOf** statement always returns a reference to the delegate. The following example associates an event handler with an event raised by an object:

```
AddHandler MyObject.Event1, AddressOf Me.MyEventHandler
```

RemoveHandler, which disconnects an event from an event handler, uses the same syntax as **AddHandler**. For example:

```
RemoveHandler MyObject.Event1, AddressOf Me.MyEventHandler
```

Addhandler Statement | Events and Event Handlers | WithEvents and the Handles Clause | Writing Event Handlers

Event Handler Example

The following example defines a class that raises an event when you call the `CauseEvent` method. This event is handled by an event handler procedure called`EventHandler`.

To run this example, add the following code to the form class of a Visual Basic .NET Windows Application project, and call the `TestEvents` procedure with an integer argument.

```
Public Class Class1
   ' Declare an event for this class.
   Public Event Event1(ByVal EventNumber As Integer)
   ' Define a method that raises an event.
   Sub CauseEvent(ByVal EventNumber As Integer)
      RaiseEvent Event1(EventNumber)
   End Sub
End Class

Protected Sub TestEvents(ByVal EventNumber As Integer)
   Dim MyObject As New Class1()
   AddHandler MyObject.Event1, AddressOf Me.EventHandler
   ' Cause the object to raise an event.
   MyObject.CauseEvent(EventNumber)
End Sub

Sub EventHandler(ByVal EventNumber As Integer)
   MessageBox.Show("Received event number " & CStr(EventNumber))
End Sub
```

Events and Event Handlers | Delegates and the AddressOf Operator | AddHandler and RemoveHandler | Writing Event Handlers

Delegates and the AddressOf Operator

Delegates are objects you can use to call the methods of other objects. They are sometimes described as *type-safe function pointers* because they are similar to function pointers used in other programming languages. But unlike function pointers, Visual Basic .NET delegates are a reference type based on the class **System.Delegate**, and can reference both shared methods — methods that can be called without a specific instance of a class — and instance methods.

Delegates are useful in situations where you need an intermediary between a calling procedure and the procedure being called. For example, you might want an object that raises events to be able to call different event handlers under different circumstances. Unfortunately, the object raising events cannot know ahead of time which event handler is handling a specific event. Visual Basic .NET lets you dynamically associate event handlers with events by creating a delegate for you when you use the **AddHandler** statement. At run time, the delegate forwards calls to the appropriate event handler.

Although you can create your own delegates, in most cases Visual Basic .NET creates the delegate and takes care of the details for you. For example, an **Event** statement implicitly defines a delegate class named `<EventName>EventHandler` as a nested class of the class containing the **Event** statement, and with the same signature as the event. The **AddressOf** statement implicitly creates an instance of a delegate. For example, the following two lines of code are equivalent:

```
AddHandler Button1.Click, AddressOf Me.Button1_Click
   ' The previous line of code is shorthand for the next line of code.
AddHandler Button1.Click, New EventHandler(AddressOf Button1_Click)
```

You can use the shorthand way of creating delegates anywhere the compiler can determine the delegate's type by the context.

Declaring Events that Use an Existing Delegate Type

In some situations, you may want to declare an event to use an existing delegate type as its underlying delegate. The following syntax demonstrates how:

```
Event AnEvent As DelegateType
```

This is useful when you want to route multiple events to the same handler.

Delegate Statement | AddressOf Operator | Events and Event Handlers | AddHandler and RemoveHandler | Writing Event Handlers | Multithreaded Applications

Delegate Example

You can use delegates for other, non-event related tasks, such as free threading or with procedures that need to call different versions of functions at compile time.

For example, suppose you have a classified-ad application that includes a list box with the names of cars. The ads are sorted by title, which is normally the make of the car. A problem you may face occurs when some cars include the year of the car before the make. The problem is that the built-in sort functionality of the list box sorts only by character codes; it places all the ads starting with dates first, followed by the ads starting with the make.

To fix this, you can create a sort procedure in a class that uses the standard alphabetic sort on most list boxes, but is able to switch at run time to the custom sort procedure for car ads. To do this, you pass the custom sort procedure to the sort class at run time, using delegates.

Each delegate class defines a constructor that is passed the specification of an object method. The following code provides an example of a parameter to such a delegate constructor:

```
AddressOf [<expression>.]<method name>
```

The compile-time type of the expression must be a class or an interface with a method by the specified name whose signature matches the signature of the delegate class. The method can be either a shared (class) method or an instance method.

You invoke the method associated with a delegate instance by calling its built-in **Invoke** method, as illustrated in the following example:

```
Delegate Sub MySubDelegate(ByVal x As Integer)
Protected Sub Test()
   Dim c2 As New class2()
   ' Test the delegate.
   c2.DelegateTest()
End Sub

Class class1
   Sub Sub1(ByVal x As Integer)
      MessageBox.Show("The value of x is: " & CStr(x))
   End Sub
End Class

Class class2
   Sub DelegateTest()
      Dim c1 As Class1
      Dim msd As MySubDelegate
      c1 = New Class1()
      ' Create an instance of the delegate.
      msd = AddressOf c1.Sub1
      msd.Invoke(10) ' Call the method.
   End Sub
End Class
```

Walkthrough: Declaring and Raising Events

This walkthrough demonstrates how to declare and raise events for a class named Widget. After you complete the steps, you might want to read the companion topic, Walkthrough: Handling Events which shows how to use events from Widget objects to provide status information in an application.

The Widget Class

Assume for the moment that you have a Widget class. Your Widget class has a method that can take a long time to execute, and you want your application to be able to put up some kind of completion indicator.

Of course, you could make the Widget object show a percent-complete dialog box, but then you would be stuck with that dialog box in every project in which you used the Widget class. A good principle of object design is to let the application that uses an object handle the user interface — unless the whole purpose of the object is to manage a form or dialog box.

The purpose of Widget is to perform other tasks, so it is better to add a `PercentDone` event, and let the procedure that calls the Widget's methods handle that event and display status updates. The `PercentDone` event also can provide a mechanism for canceling the task.

To build the code example for this topic

1. Open a new Visual Basic .NET Windows Application project, and create a form named Form1.
2. Add two buttons and a label to Form1.
3. On the **Project** menu, select **Add Class** to add a class to the project.
4. Name the objects as shown in the following table.

Object	Property	Setting
Class	**Name**	Widget
Button1	**Text**	Start Task
Button2	**Text**	Cancel
Label	**Name**, **Text**	lblPercentDone, "0 "

To declare an event for the Widget class

- In the Declarations section of your class module, declare the event using the **Event** keyword. Note that an event can have **ByVal** and **ByRef** arguments, as the Widget's `PercentDone` event demonstrates:

```
Public Event PercentDone(ByVal Percent As Single, _
                         ByRef Cancel As Boolean)
```

When the calling object receives a `PercentDone` event, the `Percent` argument contains the percentage of the task that is complete. The `Cancel` argument can be set to **True** to cancel the method that raised the event.

> **Note** You can declare event arguments just as you do arguments of procedures, with the following exceptions: Events cannot have **Optional** or **ParamArray** arguments, and events do not have return values.

The `PercentDone` event is raised by the `LongTask` method of the Widget class. `LongTask` takes two arguments: the length of time the method will pretend to be doing work, and the minimum time interval before `LongTask` pauses to raise the `PercentDone` event.

To raise the PercentDone event

1. To simplify access to the **Timer** property used by this class, add an **Imports** statement to the top of the declarations section of your class module, above the `Class Widget` statement.

```
Imports Microsoft.VisualBasic.DateAndTime
```

2. Add the following code to the Widget class:

```
Public Sub LongTask(ByVal Duration As Single, _
                    ByVal MinimumInterval As Single)
   Dim Threshold As Single
```

```
    Dim Start As Single
    Dim blnCancel As Boolean

    ' The Timer property of the DateAndTime object returns the seconds
    ' and milliseconds that have passed since midnight.
    Start = CSng(Timer)
    Threshold = MinimumInterval

    Do While CSng(Timer)< (Start + Duration)
        ' In a real application, some unit of work would
        ' be done here each time through the loop.
        If CSng(Timer)> (Start + Threshold) Then
               RaiseEvent PercentDone( _
               Threshold / Duration, blnCancel)
               ' Check to see if the operation was canceled.
               If blnCancel Then Exit Sub
               Threshold = Threshold + MinimumInterval
        End If
      Loop
End Sub
```

The Widget class raises the `PercentDone` event every `MinimumInterval` seconds when your application calls the `LongTask` method. When the event returns, `LongTask` checks to see if the `Cancel` argument was set to **True**.

A few disclaimers are necessary here. For simplicity, the `LongTask` procedure assumes you know in advance how long the task will take. This is almost never the case. Dividing tasks into chunks of even size can be difficult, and often what matters most to users is simply the amount of time that passes before they get an indication that something is happening.

You may have spotted another flaw in this sample. The **Timer** property returns the number of seconds since midnight; therefore, the application gets stuck if it is started just before midnight. A more careful approach to measuring time would take boundary conditions such as this into consideration, or avoid them altogether using properties such as **Now**.

Now that the Widget class can raise events, you can move to the next walkthrough. Walkthrough: Handling Events demonstrates how to use **WithEvents** to associate an event handler with the `PercentDone` event.

Walkthrough: Handling Events

This is the second of two topics that demonstrate how to work with events. The first topic, Walkthrough: Declaring and Raising Events, showed how to declare and raise events. This section uses the form and class from that walkthrough to show how to handle events when they take place.

The Widget class example uses traditional event-handling statements. Visual Basic .NET provides other techniques for working with events. As an exercise, you can modify this example to use the **AddHandler** and **Handles** statements.

To handle the PercentDone event of the Widget class

- Place the following code in the Declarations section of Form1:

```
Private WithEvents mWidget As Widget
Private mblnCancel As Boolean
```

The **WithEvents** keyword specifies that the variable `mWidget` is used to handle an object's events. You specify the kind of object by supplying the name of the class from which the object will be created.

The variable `mWidget` is declared in the Declarations section of Form1 because **WithEvents** variables must be module-level. This is true regardless of the type of module you place them in.

The variable `mblnCancel` is used to cancel the `LongTask` method.

Writing Code to Handle an Event

As soon as you declare a variable using **WithEvents**, the variable name appears in the left drop-down list of the module's Code editor. When you select `mWidget`, the Widget class's events appear in the right drop-down list. Selecting an event displays the corresponding event procedure, with the prefix `mWidget` and an underscore. All the event procedures associated with a **WithEvents** variable are given the variable name as a prefix.

To handle an event

1. Select `mWidget` from the left drop-down list in the Code editor.
2. Select the `PercentDone` event from the right drop-down list. The Code editor opens the `mWidget_PercentDone` event procedure.
3. Add the following code to the `mWidget_PercentDone` event handler:

```
Private Sub mWidget_PercentDone(ByVal Percent As _
                                Single, ByRef Cancel As _
                                Boolean) _
                                Handles mWidget.PercentDone
   lblPercentDone.Text = CInt(100 * Percent) & "%"
   Application.DoEvents
   If mblnCancel Then Cancel = True
End Sub
```

   Whenever the `PercentDone` event is raised, the event procedure displays the percent complete in a **Label** control. The **DoEvents** statement allows the label to repaint, and also gives the user the opportunity to click the **Cancel** button.

4. Add the following code to the `Button2_Click` event handler:

```
Private Sub Button2_Click(ByVal sender As Object, _
                          ByVal e As System.EventArgs) _
                          Handles Button2.Click
   mblnCancel = True
End Sub
```

If the user clicks the **Cancel** button while `LongTask` is running, the `Button2_Click` event is executed as soon as the **DoEvents** statement allows event processing to occur. The module-level variable `mblnCancel` is set to **True**, and the `mWidget_PercentDone` event then tests it and sets the `ByRef Cancel` argument to **True**.

Connecting a WithEvents Variable to an Object

Form1 is now set up to handle a Widget object's events. All that remains is to find a Widget somewhere.

When you declare a variable **WithEvents** at design time, no object is associated with it. A **WithEvents** variable is just like any other object variable. You have to create an object and assign a reference to it with the **WithEvents** variable.

To create an object and assign a reference to it

1. Select **Base Class Events** for Form1 from the left drop-down list in the Code editor.
2. Select the `Activated` event from the right drop-down list. The Code editor opens the `Form1_Activated` event procedure.
3. Add the following code to the `Form1_Activated` event procedure to create the Widget:

```
Private Sub Form1_Activated(ByVal sender As System.Object, _
                            ByVal e As System.EventArgs) _
                            Handles Form1.Activated
   mWidget = New Widget
End Sub
```

When this code is executed, Visual Basic creates a Widget object and connects its events to the event procedures associated with `mWidget`. From that point on, whenever the Widget raises its `PercentDone` event, the `mWidget_PercentDone` event procedure is executed.

To call the LongTask method

- Add the following code to the `Button1_Click` event handler:

```
Private Sub Button1_Click(ByVal sender As Object, _
                        ByVal e As System.EventArgs) _
                        Handles Button1.Click
   mblnCancel = False
   lblPercentDone.Text = "0%"
   lblPercentDone.Refresh()
   mWidget.LongTask(12.2, 0.33)
   If Not mblnCancel Then lblPercentDone.Text = CStr(100)& "%"
End Sub
```

Before the `LongTask` method is called, the label that displays the percent complete must be initialized, and the module-level **Boolean** flag for canceling the method must be set to **False**.

`LongTask` is called with a task duration of 12.2 seconds. The `PercentDone` event is raised once every one-third of a second. Each time the event is raised, the `mWidget_PercentDone` event procedure is executed.

When `LongTask` is done, `mblnCancel` is tested to see if `LongTask` ended normally, or if it stopped because `mblnCancel` was set to **True**. The percent complete is updated only in the former case.

To run the program

1. Press F5 to put the project in run mode.
2. Click the **Start Task** button. Each time the `PercentDone` event is raised, the label is updated with the percentage of the task that is complete.
3. Click the **Cancel** button to stop the task. Notice that the appearance of the **Cancel** button does not change immediately when you click it. The **Click** event cannot happen until the **Application.DoEvents** statement allows event processing.

You may find it instructive to run the program with F11 and step through the code a line at a time. You can clearly see how execution enters `LongTask`, and then re-enters `Form1` briefly each time the `PercentDone` event is raised.

What would happen if, while execution was back in the code of `Form1`, the `LongTask` method were called again? At worst, a stack overflow might occur if `LongTask` were called every time the event was raised.

You can cause the variable `mWidget` to handle events for a different Widget object by assigning a reference to the new Widget to `mWidget`. In fact, you can make the code in `Button1_Click` do this every time you click the button.

To handle events for a different widget

- Add the following line of code to the `Button1_Click` procedure, immediately preceding the line that reads `mWidget.LongTask(12.2, 0.33)`:

```
mWidget = New Widget      ' Create a new Widget object.
```

The code above creates a new Widget each time the button is clicked. As soon as the `LongTask` method completes, the reference to the Widget is released, and the Widget is destroyed.

A **WithEvents** variable can contain only one object reference at a time, so if you assign a different Widget object to `mWidget`, the previous Widget object's events will no longer be handled. If `mWidget` is the only object variable containing a reference to the old Widget, the object is destroyed. If you want to handle events from several Widget objects, use the **AddHandler** statement to process events from each object separately.

> **Note** You can declare as many **WithEvents** variables as you need, but arrays of **WithEvents** variables are not supported.

Interfaces in Visual Basic .NET

Interfaces define the properties, methods, and events that classes can implement. Interfaces allow you to define features as small groups of closely related properties, methods, and events; this reduces compatibility problems because you can develop enhanced implementations for your interfaces without jeopardizing existing code. You can add new features at any time by developing additional interfaces and implementations.

Versions of Visual Basic prior to Visual Basic .NET could consume interfaces but not create them directly. Visual Basic .NET introduces the **Interface** statement, which allows you to define true interfaces as distinct entities from classes, and to implement them with an improved version of the **Implements** keyword.

In This Section

Interfaces Overview
Provides an overview of what interfaces are and how Visual Basic .NET implements them.
Interface Definition
Describes how to define interfaces with the **Interface** and **End Interface** statements.
Implements Keyword
Describes how to signify that a section of code implements a specific interface.
Interface Implementation Examples
Provides three examples of interface implementation.
When to Use Interfaces
Discusses when to use interfaces instead of an inheritance hierarchy.
Creating and Implementing an Interface
Provides the steps involved in defining and implementing an interface, plus examples.
Walkthrough: Creating and Implementing Interfaces
Provides a detailed procedure that takes you through the process of defining and implementing your own interface.

Related Sections

Inheritance
Describes how Visual Basic .NET supports inheritance, allowing you to define classes that serve as the basis for derived classes.

Interfaces Overview

Interfaces, like classes, define a set of properties, methods, and events. But unlike classes, interfaces do not provide implementation. They are implemented by classes, and defined as separate entities from classes.

An interface represents a contract, in that a class that implements an interface must implement every aspect of that interface exactly as it is defined.

With interfaces, you can define features as small groups of closely related members. You can develop enhanced implementations for your interfaces without jeopardizing existing code, thus minimizing compatibility problems. You can also add new features at any time by developing additional interfaces and implementations.

Although interface implementations can evolve, interfaces themselves cannot be changed once published. Changes to a published interface may break existing code. If you think of an interface as a contract, it is clear that both sides of the contract have a role to play. The publisher of an interface agrees never to change that interface, and the implementer agrees to implement the interface exactly as it was designed.

Versions of Visual Basic prior to Visual Basic .NET could consume interfaces but not create them directly. Visual Basic .NET allows you to define true interfaces using the **Interface** statement, and to implement interfaces with an improved version of the **Implements** keyword.

Interface Definition

Interface definitions are enclosed within the **Interface** and **End Interface** statements. Following the **Interface** statement, you can add an optional **Inherits** statement that lists one or more inherited interfaces. The **Inherits** statements must precede all other statements in the declaration except comments. The remaining statements in the interface definition should be **Event**, **Sub**, **Function**, and **Property** statements. Interfaces cannot contain any implementation code or statements associated with implementation code, such as **End Sub** or **End Property**.

Interface statements are public by default, but they can also be explicitly declared as **Public**, **Friend**, **Protected**, or **Private**.

> **Note** The only valid modifiers for **Sub**, **Function**, or **Property** statements declared in an interface definition are the **Overloads** and **Default** keywords. None of the other modifiers — **Public**, **Private**, **Friend**, **Protected**, **Shared**, **Static**, **Overrides**, **MustOverride**, or **Overridable** — are allowed.

Implements Keyword

The **Implements** keyword is used to signify that a class member implements a specific interface.

An **Implements** statement requires a comma-separated list of interface members to be implemented. Generally, only a single interface member is specified, but you can specify multiple members. The specification of an interface member consists of the interface name, which must be specified in an implements statement within the class, a period, and the name of the member function, property or event to be implemented. The name of a member that implements an interface member can use any legal identifier, and is not limited to the **InterfaceName_MethodName** convention used in earlier versions of Visual Basic. For example, the following code fragment shows how to declare a subroutine named `Sub1` that implements a method of an interface:

```
Sub Sub1(ByVal i As Integer) Implements interfaceclass.interface2.Sub1
```

The parameter types and return types of the implementing member must match the interface property or member declaration in the interface. The most common way to implement an element of an interface is with a member that has the same name as the interface, as shown in the previous example.

To declare the implementation of an interface method, you can use any attributes that are legal on instance method declarations, including **Overloads**, **Overrides**, **Overridable**, **Public**, **Private**, **Protected**, **Friend**, **Protected Friend**, **MustOverride**, **Default**, and **Static**. The **Shared** attribute is not legal since it defines a class rather than an instance method.

Using **Implements**, you can also write a single method that implements multiple methods defined in an interface, as in the following example:

```
Protected Sub M1 Implements I1.M1, I1.M2, I2.M3, I2.M4
```

You can use a private member to implement a class member. When a private member implements a member of an interface, that member becomes available by way of the interface even though it is not available directly on object variables for the class.

Interface Implementation Examples

Classes that implement an interface must implement all its properties, methods, and events.

The following example defines two interfaces. The second interface, `Interface2`, inherits `Interface1` and defines an additional property and method.

```
Interface Interface1
    Sub sub1(ByVal i As Integer)
End Interface

Interface Interface2
    Inherits Interface1 ' Demonstrates interface inheritance.
    Sub M1(ByVal y As Integer)
    ReadOnly Property Num() As Integer
End Interface
```

The next example implements `Interface1`, the interface defined in the previous example:

```
Public Class ImplementationClass1
   Implements Interface1
   Sub Sub1(ByVal i As Integer) Implements Interface1.Sub1
      ' Place code here to implement this method.
    End Sub
End Class
```

The final example implements `Interface2`, including a method inherited from `Interface1`:

```
Public Class ImplementationClass2
   Implements Interface2
   Dim INum As Integer = 0
   Sub sub1(ByVal i As Integer) Implements Interface2.Sub1
      ' Place code here that implements this method.
   End Sub
   Sub M1(ByVal x As Integer) Implements Interface2.M1
      ' Place code here to implement this method.
   End Sub

   ReadOnly Property Num() As Integer Implements _
      Interface2.Num
      Get
        Num = INum
      End Get
   End Property
End Class
```

When to Use Interfaces

Interfaces are a powerful programming tool because they allow you to separate the definition of objects from their implementation, allowing your objects to evolve without risk of breaking existing applications. Both interfaces and class inheritance each have advantages and disadvantages, and you may end up using a combination of both in your projects. This topic and When to Use Inheritance will help you determine which approach is best for your situation.

Safe Changes to Code

Interfaces eliminate a significant problem of class inheritance: the likelihood of breaking code when you make post-implementation changes to your design. Even though class inheritance allows your classes to inherit implementation from a base class, it also forces you to make most of your design decisions when the class is first published. If your original assumptions turn out to be incorrect, you cannot always change your code safely in later versions.

For instance, suppose you define a method of a base class that expects an **Integer** argument, and then later determine that the argument should be of the **Long** data type. You cannot safely change the original class, because applications designed for classes derived from the original may not compile correctly. This problem can be magnified because a single base class can affect hundreds of subclasses.

One solution is to define a new method that overloads the original and that takes an argument of type **Long**. However, this might not be satisfactory because a derived class may need to override the method that takes the integer, and may not function properly if the method that takes a **Long** is not overridden also. Interfaces solve this problem by allowing you to publish an updated interface that accepts the new data type.

Flexibility in Implementation

There are several other reasons why you might want to use interfaces instead of class inheritance:

- Interfaces are better suited to situations in which your applications require many possibly unrelated object types to provide certain functionality.
- Interfaces are more flexible than base classes because you can define a single implementation that can implement multiple interfaces.
- Interfaces are better in situations in which you do not need to inherit implementation from a base class.
- Interfaces are useful in cases where you cannot use class inheritance. For example, structures cannot inherit from classes, but they can implement interfaces.

Creating and Implementing an Interface

As explained in Interfaces Overview, interfaces describe the properties, methods, and events of a class without providing any implementation.

To create an interface

1. Define your interface by adding code to it that begins with the **Interface** keyword and the name of the interface, and ends with the **End Interface** statement. For example, the following code defines an interface named `Encryption`:

```
Interface Encryption
End Interface
```

2. Add statements that define the properties, methods, and events your interface supports. For example, the following code defines two methods, a property, and an event:

```
Interface Encryption
   Function Encrypt(ByVal estring As String) As String
   Function Decrypt(ByVal dstring As String) As String
   Property EncryptionBits() As Integer
   Event FinishedDecoding(ByVal RetVal As Integer)
End Interface
```

To implement an interface

1. If the interface you are implementing is not part of your project, add a reference to the assembly containing the interface.
2. Create a new class that implements your interface, and include the **Implements** keyword in the line following the class name. For example, to implement the `Encryption` interface using **Xor** encryption, you could name the implementation class `XorEnc`, as in the following code:

```
Class XorEnc
   Implements Encryption
End Class
```

3. Add procedures to implement the properties, methods, and events of the class as in the following code, which builds on the example in the previous step:

```
Class XorEnc
   Implements Encryption
   Event FinishedDecoding(ByVal RetVal As Integer) _
      Implements Encryption.FinishedDecoding

   Function Encrypt(ByVal estring As String) _
      As String Implements Encryption.Encrypt
      ' Place code to perform Xor encryption here.
   End Function
   Function Decrypt(ByVal dstring As String) _
      As String Implements Encryption.Decrypt
      ' Place code to perform Xor decryption here.
   End Function

   Property EncryptionBits() As Integer _
      Implements Encryption.EncryptionBits
      Get
         'Place code to return the value of this property here.
      End Get
      Set
         'Place code to set this property here.
      End Set
```

```
    End Property
End Class
```

Note This walkthrough uses simple Xor encryption to demonstrate interface implementation. You should use a more sophisticated form of encryption to store sensitive information.

Walkthrough: Creating and Implementing Interfaces

Interfaces describe the characteristics of properties, methods, and events, but leave the implementation details up to structures or classes.

This walkthrough demonstrates how to declare and implement an interface.

To define an interface

1. Open a new Windows Application project by clicking **New** on the **File** menu, and then clicking **Project**. The **New Project** dialog box appears.
2. Select **Visual Basic Projects** in the **Project Types** pane.
3. Select Windows Application from the list of Visual Basic project templates.
4. Add a new module to the project by clicking **Add Module** on the **Project** menu.
5. Name the new module `Module1.vb` and click **Open**. The code for the new module is displayed.
6. Define an interface named `MyInterface` within `Module1` by typing `Interface MyInterface` between the **Module** and **End Module** statements and then pressing ENTER. The code editor indents the **Interface** keyword and adds an **End Interface** statement to form a code block.
7. Define a property, method, and event for the interface by placing the following code between the **Interface** and **End Interface** statements:

```
    Property Prop1() As Integer
    Sub Method1(ByVal X As Integer)
    Event Event1()
```

You may notice that the syntax used to declare interface members is different from the syntax used to declare class members. This difference reflects the fact that interfaces cannot contain implementation code.

To implement the interface

1. Add a class named `ImplementationClass` by adding the following statement to `Module1` after the `End Interface` statement but before the `End Module` statement and then pressing **ENTER**:

```
Class ImplementationClass
```

   If you are working within the integrated development environment, the code editor will supply a mathching `End Class` statement when you press **ENTER**.

2. Add the following **Implements** statement to `ImplementationClass`, which names the interface the class implements:

```
Implements MyInterface
```

   When listed separately from other items at the top of a class or structure, the **Implements** statement indicates that the class or structure implements an interface. If you are working within the integrated development environment, the Code Editor may underline the word `MyInterface` and warn you that this class must implement all the members of the interface `MyInterface`. The next two steps in this walkthrough implement these members and take care of this warning.

3. Add the following code to `ImplementationClass` to implement `Event1`.

```
Event Event1() Implements MyInterface.Event1
```

   This code contains an **Event** statement to implement `Event1`, and an **Implements** statement that names the interface and interface member being implemented.

4. Add the following code to `ImplementationClass` to implement the remaining members of the interface:

```
Private pval As Integer ' Holds the value of the property.
Property Prop1() As Integer Implements MyInterface.Prop1
   Get
      Return pval
```

```
    End Get
    Set(ByVal Value As Integer)
       pval = Value
    End Set
End Property

Sub Method1(ByVal X As Integer) Implements MyInterface.Method1
    MsgBox("The X parameter for Method1 is " & X)
    RaiseEvent Event1()
    ' Add more code to implement this method.
End Sub
```

For each member being implemented in this code, an **Implements** statement indicates the name of the interface and member being implemented.

To test the implementation of the interface

1. Right click the startup form for your project in the Solution Explorer and click **View Code**. The editor displays the class for your startup form. By default the startup form is called `Form1`.
2. Add the following event handler to the `Form1` class to handle events raised by instances of `ImplementationClass`:

```
Sub EventHandler()
    MsgBox("The event handler caught the event.")
End Sub
```

3. Add a subroutine named `Test` to the `Form1` class to test the implementation class:

```
Sub Test()
'   Create an instance of the class.
    Dim T As New ImplementationClass()
'   Create a variable of type MyInterface.
    Dim I As MyInterface
'   Assign the class instance to the interface.
'   Calls to the interface members are
'   executed through the class instance.
    I = T
'   Associate an event handler with an event raised by the object.
    AddHandler I.Event1, AddressOf EventHandler
    I.Prop1 = 9 'Set a property.
    MsgBox("Prop1 was set to " & I.Prop1) ' Read the property.
'   Test the method and raise an event.
    I.Method1(5)
End Sub
```

The `Test` procedure creates an instance of the class that implements `MyInterface`, creates a variable of the interface's type, associates an event handler with the event raised by the instance, sets a property, and runs a method through the interface.

4. Add code to call the `Test` procedure from the `Form1_Load` procedure of your startup form:

```
Private Sub Form1_Load(ByVal sender As System.Object, _
                       ByVal e As System.EventArgs) _
                       Handles MyBase.Load
    Test() ' Test the class.
End Sub
```

5. Run the `Test` procedure by pressing F5. The message "Prop1 was set to 9" is displayed. After you click OK, the message "The X parameter for Method1 is 5" is displayed. Click OK and the message "The event handler caught the event" is displayed.

Inheritance

Visual Basic .NET supports *inheritance*, the ability to define classes that serve as the basis for derived classes. Derived classes inherit, and can extend, the properties, methods, and events of the base class. Derived classes can also override inherited methods with new implementations. All classes created with Visual Basic .NET are inheritable by default.

Inheritance allows you to write and debug a class once, and then reuse that code over and over as the basis of new classes. Inheritance also allows you to use inheritance-based *polymorphism*, the ability to define classes that can be used interchangeably by client code at run time, but with functionally different, yet identically named methods or properties.

Object-Oriented Programming in Visual Basic
Introduces the concepts of object-oriented programming as they are used in Visual Basic .NET.

Inheritance Basics

The **Inherits** statement is used to declare a new class, called a *derived class*, based on an existing class, known as a *base class*. Derived classes inherit, and can extend, the properties, methods, events, fields, and constants defined in the base class. The following section describes some of the rules for inheritance, and the modifiers you can use to change the way classes inherit or are inherited:

- All classes are inheritable by default unless marked with the **NotInheritable** keyword. Classes can inherit from other classes in your project or from classes in other assemblies that your project references.
- Unlike languages that permit multiple inheritance, Visual Basic .NET permits only single inheritance in classes; that is, derived classes can have only one base class. Although multiple inheritance is not allowed in classes, classes *can* implement multiple interfaces, which can effectively accomplish the same ends.
- To prevent exposing restricted items in a base class, the access type of a derived class must be equal to or more restrictive than its base class. For example, a **Public** class cannot inherit a **Friend** or a **Private** class, and a **Friend** class cannot inherit a **Private** class.

Inheritance Modifiers

Visual Basic .NET introduces the following class-level statements and modifiers to support inheritance:

- **Inherits** statement — Specifies the base class.
- **NotInheritable** modifier — Prevents programmers from using the class as a base class.
- **MustInherit** modifier — Specifies that the class is intended for use as a base class only. Instances of **MustInherit** classes cannot be created directly; they can only be created as base class instances of a derived class. (Other programming languages, such as C++ and C#, use the term *abstract class* to describe such a class.)

Overriding Properties and Methods in Derived Classes

By default, a derived class inherits methods from its base class. If an inherited property or method needs to behave differently in the derived class it can be *overridden*; that is, you can define a new implementation of the method in the derived class. The following modifiers are used to control how properties and methods are overridden:

- **Overridable** — Allows a property or method in a class to be overridden in a derived class.
- **Overrides** — Overrides an **Overridable** property or method defined in the base class.
- **NotOverridable** — Prevents a property or method from being overridden in an inheriting class. **Public** methods are **NotOverridable** by default.
- **MustOverride** — Requires that a derived class override the property or method. When the **MustOverride** keyword is used, the method definition consists of just the **Sub**, **Function**, or **Property** statement. No other statements are allowed, and specifically there is no **End Sub** or **End Function** statement. **MustOverride** methods must be declared in **MustInherit** classes.

For more information about overriding methods see Overriding Properties and Methods.

The MyBase Keyword

You can use the **MyBase** keyword to call methods in a base class when overriding methods in a derived class. For example, suppose you are designing a derived class that overrides a method inherited from the base class. The overridden method can call the method in the base class and modify the return value as shown in the following code fragment:

```
Class DerivedClass
   Inherits BaseClass
   Public Overrides Function CalculateShipping(ByVal Dist As Double, _
                                   ByVal Rate As Double) As Double
      ' Call the method in the base class and modify the return value.
      Return MyBase.CalculateShipping(Dist, Rate) * 2
   End Function
End Class
```

The following list describes restrictions on using **MyBase**:

- **MyBase** refers to the immediate base class and its inherited members. It cannot be used to access **Private** members in the

class.

- **MyBase** is a keyword, not a real object. **MyBase** cannot be assigned to a variable, passed to procedures, or used in an **Is** comparison.
- The method that **MyBase** qualifies does not need to be defined in the immediate base class; it may instead be defined in an indirectly inherited base class. In order for a reference qualified by **MyBase** to compile correctly, some base class must contain a method matching the name and types of parameters appearing in the call.
- You cannot use **MyBase** to call **MustOverride** base class methods.
- **MyBase** cannot be used to qualify itself. Therefore, the following code is illegal:

```
MyBase.MyBase.BtnOK_Click()   ' Syntax error.
```

- **MyBase** cannot be used in modules.
- **MyBase** cannot be used to access base class members that are marked as **Friend** if the base class is in a different assembly.

The MyClass Keyword

The **MyClass** keyword allows you to call an **Overridable** method implemented in your class and make sure that implementation of the method in this class is called rather than an overridden method in a derived class.

- **MyClass** is a keyword, not a real object. **MyClass** cannot be assigned to a variable, passed to procedures, or used in an **Is** comparison.
- **MyClass** refers to the containing class and its inherited members.
- **MyClass** can be used as a qualifier for **Shared** members.
- **MyClass** cannot be used in standard modules.
- **MyClass** can be used to qualify a method that is defined in a base class and that has no implementation of the method provided in that class. Such a reference has the same meaning as **MyBase.Method**.

Using Inherits to Create a Derived Class | Inherits Statement | Overriding Properties and Methods | Language Changes in Visual Basic

Using Inherits to Create a Derived Class

The **Inherits** statement causes a class to inherit all the non-private members of the specified class.

To inherit from another class

- Add an **Inherits** statement with the name of a class you want to use as a base class as the first statement in your derived class. The **Inherits** statement must be the first non-comment statement after the class statement.

Inheritance Example

The following example defines two classes. The first class is a base class that has two methods. The second class inherits both methods from the base class, overrides the second method, and defines a field named `Field`.

```
Class Class1
   Sub Method1()
      MessageBox.Show("This is a method in the base class.")
   End Sub
   Overridable Sub Method2()
      MessageBox.Show("This is another method in the base class.")
   End Sub
End Class

Class Class2
   Inherits Class1
   Public Field2 as Integer
   Overrides Sub Method2()
      Messagebox.Show("This is a method in a derived class.")
   End Sub
End Class

Protected Sub TestInheritance()
   Dim C1 As New class1()
   Dim C2 As New class2()
   C1.Method1() ' Calls a method in the base class.
   C1.Method2() ' Calls another method from the base class.
   C2.Method1() ' Calls an inherited method from the base class.
   C2.Method2() ' Calls a method from the derived class.
End Sub
```

When you run the procedure `TestInheritance`, you see the following messages:

```
"This is a method in the base class."
"This is another method in the base class."
"This is a method in the base class."
"This is a method in a derived class."
```

When to Use Inheritance

Inheritance is a useful programming concept, but it is easy to use inappropriately. Often interfaces do the job better. This topic and When to Use Interfaces help you understand when each approach should be used.

Inheritance is a good choice when:

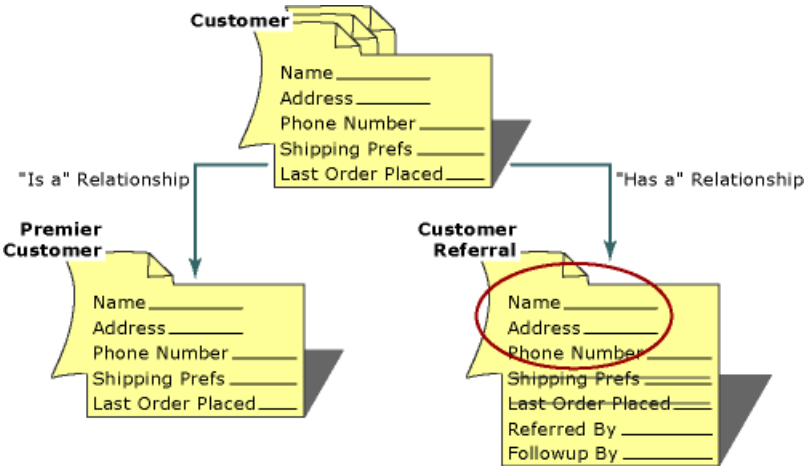
- Your inheritance hierarchy represents an *is-a* relationship and not a *has-a* relationship.
- You can reuse code from the base classes.
- You need to apply the same class and methods to different data types.
- The class hierarchy is reasonably shallow, and other developers are not likely to add many more levels.
- You want to make global changes to derived classes by changing a base class.

These considerations are discussed in order below.

Inheritance and "Is a" Relationships

Two ways to show class relationships in object-oriented programming are "is a" and "has a" relationships. In an "is a" relationship, the derived class is clearly a kind of the base class. For example, a class named PremierCustomer represents an "is a" relationship with a base class named Customer because a premier customer is a customer. However, a class named CustomerReferral represents a "has a" relationship with the Customer class because a customer referral has a customer, but a customer referral is not a kind of customer.

Objects in an inheritance hierarchy should have an "is a" relationship with their base class because they inherit the fields, properties, methods, and events defined in the base class. Classes that represent a "has a" relationship with other classes are not suited to inheritance hierarchies because they may inherit inappropriate properties and methods. For example, if the CustomerReferral class were derived from the Customer class discussed previously, it might inherit properties that make no sense, such as ShippingPrefs and LastOrderPlaced. "Has a" relationships such as this should be represented using unrelated classes or interfaces. The following illustration shows examples of both "is a" and "has a" relationships.



Base Classes and Code Reuse

Another reason to use inheritance is the advantage of code reuse. Well-designed classes can be debugged once and used over and over as a basis for new classes.

A common example of effective code reuse is in connection with libraries that manage data structures. Suppose, for example, that you have a large business application that manages several kinds of in-memory lists. One is an in-memory copy of your customer database, read in from a database at the beginning of the session for speed. The data structure might look something like the following:

```
Class CustomerInfo
   Public PreviousCustomer As CustomerInfo
   Public NextCustomer As CustomerInfo
   Public ID As Integer
   Public FullName As String

   Function InsertCustomer As CustomerInfo
      ' Add code to add a CustomerInfo item to the list.
   End Function
```

```
    Function DeleteCustomer As CustomerInfo
      ' Add code to remove a CustomerInfo item from the list.
    End Function

   Function GetNextCustomer As CustomerInfo
      ' Add code to get the next CustomerInfo item from the list.
   End Function

   Function GetPrevCustomer As CustomerInfo
        'Add code to get the previous CustomerInfo item from the list.
   End Function
End Class
```

Your application may also have a similar list of products the user has added to a shopping cart list, as shown in the following code fragment:

```
Class ShoppingCartItem
   Public PreviousItem As ShoppingCartItem
   Public NextItem As ShoppingCartItem
   Public ProductCode As Integer
   Function GetNextItem As ShoppingCartItem
      ' Add code to get the next ShoppingCartItem from the list.
   End Function
End Class
```

You can see a pattern here: two lists behave the same way (insertions, deletions, and retrievals) but operate on different data types. Maintaining two code bases to perform essentially the same functions is asking for trouble. The most efficient solution is to factor out the list management into its own class, and then inherit from that class for different data types:

```
Class ListItem
   Public PreviousItem As ListItem
   Public NextItem As ListItem
   Function GetNextItem() As ListItem
      ' Add code to get the next item in the list.
   End Function
   Function InsertNextItem As ListItem
      ' Add code to add a item to the list.
   End Function

    Function DeleteNextItem As ListItem
      ' Add code to remove a item from the list.
    End Function

   Function GetPrevItem As ListItem
        'Add code to get the previous item from the list.
   End Function

End Class
```

The `ListItem` class needs only to be debugged once. Then you can build classes that use it without ever having to think about list management again. For example:

```
Class CustomerInfo
   Inherits ListItem
   Public ID As Integer
   Public FullName As String
End Class
Class ShoppingCartItem
   Inherits ListItem
   Public ProductCode As Integer
End Class
```

Although inheritance-based code reuse is powerful tool, it also has associated risks. Even the best-designed systems sometimes

change in ways the designers could not foresee. Changes to an existing class hierarchy can sometime have unintended consequences; some examples are discussed in "The Fragile Base Class Problem," in Class Design Changes After Deployment.

Interchangeable Derived Classes

Derived classes in a class hierarchy can sometimes be used interchangeably with their base class, a process called inheritance-based polymorphism. This approach combines the best features of interface-based polymorphism with the option of reusing or overriding code from a base class.

An example where this can be useful is in a drawing package. For example, consider the following code fragment, which does not use inheritance:

```
Sub Draw(ByVal Shape As DrawingShape, ByVal X As Integer, _
      ByVal Y As Integer, ByVal Size As Integer)
   Select Case Shape.Type
      Case shpCircle
      ' Circle drawing code here.
      Case shpLine
      ' Line drawing code here.
   End Select
End Sub
```

This approach poses some problems. If someone decides to add an ellipse option later, it will be necessary to alter the source code; it is possible that your target users will not even have access to your source code. A more subtle problem is that drawing an ellipse requires another parameter (ellipses have both a major and a minor diameter) that would be irrelevant to the line case. If someone then wants to add a polyline (multiple connected lines), then another parameter would be added, and it would be irrelevant to the other cases.

Inheritance solves most of these problems. Well-designed base classes leave the implementation of specific methods up to the derived classes, so that any kind of shape can be accommodated. Other developers can implement methods in derived classes by using the documentation for the base class. Other class items (such as the x- and y-coordinates) can be built into the base class because all descendants use them. For example, `Draw` could be a **MustOverride** method:

```
MustInherit Class Shape
   Public X As Integer
   Public Y As Integer
   MustOverride Sub Draw()
End Class
```

Then you could add to that class as appropriate for different shapes. For example, a `Line` class might only need a `Length` field:

```
Class Line
   Inherits Shape
   Public Length As Integer
   Overrides Sub Draw()
       ' Place code here to implement Draw for this shape.
   End Sub
End Class
```

This approach is useful because other developers, who do not have access to your source code, can extend your base class with new derived classes as needed. For example, a class named `Rectangle` could be derived from the `Line` class:

```
Class Rectangle
   Inherits Line
   Public Width As Integer
   Overrides Sub Draw()
      ' Place code here to implement Draw for the Rectangle shape.
   End Sub
End Class
```

This example shows how you can move from general-purpose classes to very specific classes by adding implementation details at

each level.

At this point it might be good to reevaluate if the derived class truly represents a "is a" relationship, or have we inadvertently used a "has a" relationship. If the new rectangle class is just composed of lines, then inheritance is not the best choice. However, if the new rectangle is a line with a width property, then the "is a" relationship is maintained.

Shallow Class Hierarchies

Inheritance is best suited for relatively shallow class hierarchies. Excessively deep and complex class hierarchies can be difficult to develop. The decision to use a class hierarchy involves weighing the benefits of using a class hierarchy against complexity. As a general rule, you should limit hierarchies to six levels or fewer. However, the maximum depth for any particular class hierarchy depends on a number of factors, including the amount of complexity at each level.

Global Changes to Derived Classes Through the Base Class

One of the most powerful features of inheritance is the ability to make changes in a base class that propagate to derived classes. When used carefully, you can update the implementation of a single method, and dozens, or even hundreds of derived classes can use the new code. However, this can be a dangerous practice because such changes may cause problems with inherited classes designed by other people. Care must be taken to ensure that the new base class is compatible with classes that use the original. You should specifically avoid changing the name or type of base class members.

Suppose, for example, that you design a base class with a field of type **Integer** to store zip code information, and other developers have created derived classes that use the inherited zip code field. Suppose further that your zip code field stores 5 digits, and the post office has expanded zip codes with a hyphen and 4 more digits. In a worst-case scenario, you could modify the field in the base class to store a 10-character string, but other developers would need to change and recompile the derived classes to use the new size and data type.

The safest way to change a base class is to simply add new members. For example, you could add a new field to store the additional 4 digits in the zip code example discussed previously. That way, client applications can be updated to use the new field without breaking existing applications. The ability to extend base classes in an inheritance hierarchy is an important benefit that does not exist with interfaces.

When to Use Interfaces | Class Design Changes After Deployment

Inheritance and the .NET Framework

Visual Studio .NET applications can use many of the classes found in the .NET Framework as base classes. Attribute classes, for instance, are always based on the class **System.Attribute**. Other useful .NET Framework base classes include **System.ComponentModel.Component**, which is inherited from to define components, and **System.Exception**, which is inherited from to define custom exception classes.

The .NET Framework is more than a source for base classes; it ensures compatibility between classes created with different programming languages. Visual Basic .NET classes can inherit from classes in assemblies created by any language supported by Visual Studio .NET. The classes you create in Visual Basic .NET can also be used as base classes by other .NET programming languages.

Walkthrough: Implementing Inheritance with COM Objects | Inheritance and the Base Object Class | When to Use Inheritance

Walkthrough: Implementing Inheritance with COM Objects

You can derive Visual Basic .NET classes from **Public** classes in COM objects, even those created with previous versions of Visual Basic. The properties and methods of classes inherited from COM objects can be overridden or overloaded in the same way that properties and methods of any other base class can be overridden or overloaded. Inheritance from COM objects is useful when you have an existing class library that you do not want to recompile.

The following procedure shows how to use Visual Basic 6.0 to create a COM object containing a class, and then use it as a base class in Visual Basic .NET.

To build the COM object used in this walkthrough

1. In Visual Basic 6.0, open a new ActiveX DLL project. A project named **Project1** is created with a class named `Class1`.
2. In the Project Explorer, right-click **Project1**, and then click **Project1 Properties**. The **Project Properties** dialog box is displayed.
3. On the **General** tab of the **Project Properties** dialog box, change the project name by typing `ComObject1` in the **Project Name** field.
4. In the Project Explorer, right-click `Class1`, and then click **Properties**. The **Properties** window for the class is displayed.
5. Change the **Name** property to `MathFunctions`.
6. In the Project Explorer, right-click `MathFunctions`, and then click **View Code**. The Code editor is displayed.
7. Add a local variable to hold the property value:

```
' Local variable to hold property value
Private mvarProp1 As Integer
```

8. Add Property **Let** and Property **Get** property procedures:

```
Public Property Let Prop1(ByVal vData As Integer)
'Used when assigning a value to the property.
    mvarProp1 = vData
End Property
Public Property Get Prop1() As Integer
'Used when retrieving a property's value.
    Prop1 = mvarProp1
End Property
```

9. Add a function:

```
Function AddNumbers(SomeNumber As Integer, _
                    AnotherNumber As Integer) As Integer
   AddNumbers = SomeNumber + AnotherNumber
End Function
```

10. Create and register the COM object by selecting **Make ComObject1.dll** from the **File** menu.

> **Note** You can also create COM objects using Visual Basic .NET. For details, see COM Interoperability in Visual Basic and Visual C#.

Interop Assemblies

In the following procedure, you will create an interop assembly, which acts as a bridge between unmanaged code (such as a COM object) and the managed code Visual Studio .NET uses. The interop assembly that Visual Basic creates handles many of the details of working with COM objects, such as *interop marshaling,* the process of packaging parameters and return values into equivalent data types as they move to and from COM objects. The reference in the Visual Basic .NET application points to the interop assembly, not the actual COM object.

To use a COM object with Visual Basic .NET

1. Open a new Visual Basic .NET Windows Application project.
2. On the **Project** menu, click **Add Reference**.

The **Add Reference** dialog box is displayed.

3. On the **COM** tab, double click `ComObject1` in the **Component Name** list and click OK.
4. On the **Project** menu, click **Add New Item**.

   The **Add New Item** dialog box is displayed.

5. In the **Templates** pane, click **Class**.

   The default file name, `Class1.vb`, appears in the **Name** field. Change this field to MathClass.vb and click **Open**. This will create a class named `MathClass`, and display its code.

6. Add the following code to the top of `MathClass` to inherit from the COM class.

```
' The inherited class is called MathFunctions in the base class,
' but the interop assembly appends the word Class to the name.
Inherits ComObject1.MathFunctionsClass
```

7. Overload and extend the inherited members by adding the following code to `MathClass`:

```
'  This method overloads the method AddNumbers from the base class.
   Overloads Function AddNumbers(ByRef SomeNumber As Integer, _
                                 ByRef AnotherNumber As Integer _
                                 ) As Integer
      AddNumbers = SomeNumber + AnotherNumber
   End Function

'  The following function extends the inherited class.
   Function SubtractNumbers(ByVal SomeNumber As Integer, _
                            ByVal AnotherNumber As Integer) As Integer
      SubtractNumbers = AnotherNumber - SomeNumber
   End Function
```

The new class inherits the properties of the base class in the COM object, overloads a method, and defines a new method to extend the class.

To test the inherited class

1. Add a button to your startup form, and then double-click it to view its code.
2. In the button's **Click** event handler procedure, add the following code to create an instance of MathClass and call the overloaded methods:

```
Dim Result1 As Integer
Dim Result2 As Short
Dim Result3 As Integer
Dim MathObject As New MathClass()
Result1 = MathObject.AddNumbers(4S, 2S) ' Add two Shorts.
Result2 = MathObject.AddNumbers(4, 2) 'Add two Integers.
Result3 = MathObject.SubtractNumbers(2, 4) ' Subtract 2 from 4.
MathObject.Prop1 = 6 ' Set an inherited property.

MsgBox("Calling the AddNumbers method in the base class " & _
       "using Short type numbers 4 and 2 = " & Result1)
MsgBox("Calling the overloaded AddNumbers method using " & _
       "Integer type numbers 4 and 2 = " & Result2)
MsgBox("Calling the SubtractNumbers method " & _
       "subtracting 2 from 4 = " & Result3)
MsgBox("The value of the inherited property is " & _
        MathObject.Prop1)
```

3. Run the project by pressing F5.

When you click the button on the form, the `AddNumbers` method is first called with **Short** data type numbers, and Visual Basic .NET chooses the appropriate method from the base class. The second call to `AddNumbers` is directed to the overload method from `MathClass`. The third call calls the `SubtractNumbers` method, which extends the class. The property in the base class is set, and the value is displayed.

Data Type Differences

You may have noticed that the overloaded `AddNumbers` function appears to have the same data type as the method inherited from the COM object's base class. This is because the base class method's arguments and parameters are defined as 16-bit integers in Visual Basic 6.0, but they are exposed as 16-bit integers of type **Short** in Visual Basic .NET. The new function accepts 32-bit integers, and overloads the base class function.

When working with COM objects, it is important to verify the size and data types of parameters. For example, when using a COM object that accepts a Visual Basic 6.0 collection object as an argument, you cannot provide a Visual Basic .NET collection. For a more information about data type changes, see Language Changes in Visual Basic.

Overriding Properties and Methods Inherited from COM classes

Properties and methods inherited from COM classes can be overridden, meaning that you can declare a local property or method that replaces a property or method inherited from a base COM class. The rules for overriding inherited COM properties are similar to the rules for overriding other properties and methods with the following exceptions:

- If you override any property or method inherited from a COM class, you must override all the other inherited properties and methods.
- Properties that use ByRef parameters cannot be overridden.

Inheritance and the Base Object Class

Almost everything you do with Visual Basic .NET involves objects, including some entities not normally thought of as objects, such as strings and integers. All objects in Visual Basic .NET are derived from, and inherit methods from, a base class called **System.Object**. The **System.Object** class provides a common base class for all objects in the .NET framework, ensuring interoperability of objects developed using Visual Studio .NET. New classes implicitly inherit the **System.Object** class; it is never necessary to explicitly name this class with an Inherits statement.

Among the methods that objects inherit from **System.Object**, one of the most useful is **Object.GetType**, which is used to return the exact type of the current object.

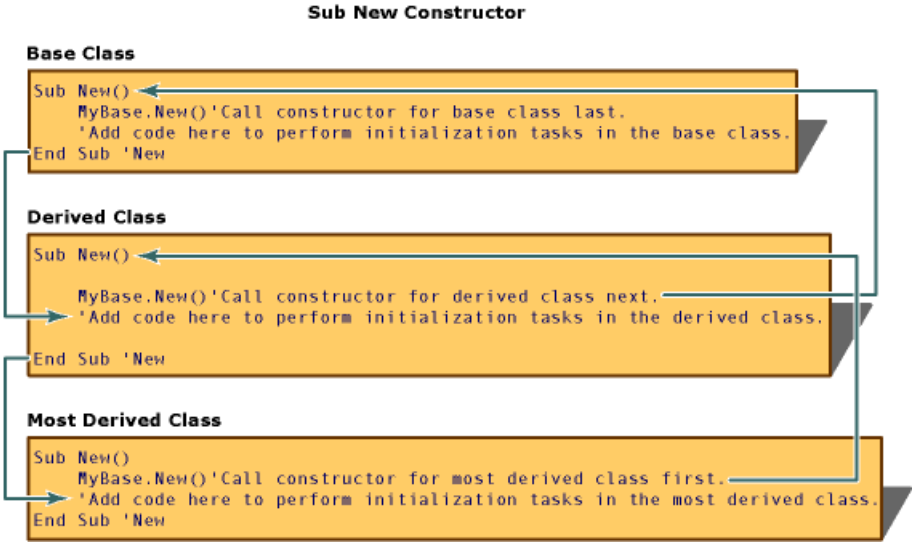
How New and Finalize Methods Work in a Class Hierarchy

Whenever an instance of a class is created, the common language runtime (CLR) attempts to execute a procedure named **New**, if it exists in that object. **New** is a type of procedure called a *constructor* that is used to initialize new objects before any other code in an object executes. A **New** constructor can be used to open files, connect to databases, initialize variables, and take care of any other tasks that need to be done before an object can be used.

When an instance of a derived class is created, the **Sub New** constructor of the base class executes first, followed by constructors in derived classes. This happens because the first line of code in a **Sub New** constructor uses the syntax `MyBase.New()` to call the constructor of the class immediately above itself in the class hierarchy. The **Sub New** constructor is then called for each class in the class hierarchy until the constructor for the base class is reached. At that point, the code in the constructor for the base class executes, followed by the code in each constructor in all derived classes and the code in the most derived classes is executed last.



When an object is no longer needed, the CLR calls the **Finalize** method for that object before freeing its memory. The **Finalize** method is called a *destructor* because it performs cleanup tasks, such as saving state information, closing files and connections to databases, and other tasks that must be done before releasing the object.

When the **Sub Finalize** method of a derived class is called, it first performs any cleanup tasks that are needed and then uses the syntax `MyBase.Finalize()` to explicitly call the **Sub Finalize** method of its base class. Therefore, **Sub Finalize** methods run from the most-derived classes first, and execute code in the base class last.

Polymorphism

Polymorphism refers to the ability to define multiple classes with functionally different, yet identically named methods or properties that can be used interchangeably by client code at run time.

In This Section

How Visual Basic Provides Polymorphism
Illustrates different approaches to polymorphism.
Inheritance-Based Polymorphism
Discusses using inheritance to achieve polymorphism.
Interface-Based Polymorphism
Discusses using interfaces to achieve polymorphism.

Related Sections

When To Use Interfaces
Discusses when to use interfaces instead of an inheritance hierarchy.
When to Use Inheritance
Provides information about when you should use inheritance instead of interfaces.

How Visual Basic Provides Polymorphism

Traditionally, polymorphism in Visual Basic was accomplished with interfaces, and interfaces can still be used for this purpose. Now, however, Visual Basic .NET provides the option of using inheritance to provide polymorphism as well. As with other issues in object-oriented programming, the option to use depends on your specific requirements. In general, use inheritance when you want to create baseline functionality that derived classes can extend; use interfaces in situations where similar functionality needs to be provided by multiple implementations that have little in common.

See Also

Inheritance-Based Polymorphism | Interface-Based Polymorphism | Designing an Inheritance Hierarchy

Inheritance-Based Polymorphism

Most object-oriented programming systems provide polymorphism through inheritance. Inheritance-based polymorphism involves defining methods in a base class and overriding them with new implementations in derived classes.

For example, you could define a class, `BaseTax`, that provides baseline functionality for computing sales tax in a state. Classes derived from `BaseTax`, such as `CountyTax` or `CityTax`, could implement methods such as `CalculateTax` as appropriate.

Polymorphism comes from the fact that you could call the `CalculateTax` method of an object belonging to any class that derived from `BaseTax`, without knowing which class the object belonged to.

The `TestPoly` procedure in the following example demonstrates inheritance-based polymorphism:

```
Const StateRate As Double = 0.053 ' %5.3 State tax
Const CityRate As Double = 0.028  ' %2.8 City tax
Public Class BaseTax
   Overridable Function CalculateTax(ByVal Amount As Double) As Double
      Return Amount * StateRate ' Calculate state tax.
   End Function
End Class

Public Class CityTax
   ' This method calls a method in the base class
   ' and modifies the returned value.
   Inherits BaseTax
   Private BaseAmount As Double
   Overrides Function CalculateTax(ByVal Amount As Double) As Double
      ' Some cities apply a tax to the total cost of purchases,
      ' including other taxes.
      BaseAmount = MyBase.CalculateTax(Amount)
      Return CityRate * (BaseAmount + Amount) + BaseAmount
   End Function
End Class

Sub TestPoly()
    Dim Item1 As New BaseTax()
    Dim Item2 As New CityTax()
    ShowTax(Item1, 22.74) ' $22.74 normal purchase.
    ShowTax(Item2, 22.74) ' $22.74 city purchase.
 End Sub

Sub ShowTax(ByVal Item As BaseTax, ByVal SaleAmount As Double)
   ' Item is declared as BaseTax, but you can
   ' pass an item of type CityTax instead.
   Dim TaxAmount As Double
   TaxAmount = Item.CalculateTax(SaleAmount)
      MsgBox("The tax is: " & Format(TaxAmount, "C"))
End Sub
```

In this example, the `ShowTax` procedure accepts a parameter named `Item` of type `BaseTax`, but you can also pass any of the classes derived from the shape class, such as `CityTax`. The advantage of this design is that you can add new classes derived from the `BaseTax` class without changing the client code in the `ShowTax` procedure.

Interface-Based Polymorphism | Designing an Inheritance Hierarchy

Interface-Based Polymorphism

Interfaces provide another way you can accomplish polymorphism in Visual Basic .NET. Interfaces describe properties and methods like classes, but unlike classes, interfaces cannot provide any implementation. Multiple interfaces have the advantage of allowing systems of software components to evolve without breaking existing code.

To achieve polymorphism with interfaces, you implement an interface in different ways in several classes. Client applications can use either the old or the new implementations in exactly the same way. The advantage to interface based polymorphism is that you do not need to re-compile existing client applications to get them to work with new interface implementations.

The following example defines an interface named `Shape2` that is implemented in a class named `RightTriangleClass2` and `RectangleClass2`. A procedure named `ProcessShape2` calls the `CalculateArea` method of instances of `RightTriangleClass2` or `RectangleClass2`:

```
Sub TestInterface()
   Dim RectangleObject2 As New RectangleClass2()
   Dim RightTriangleObject2 As New RightTriangleClass2()
   ProcessShape2(RightTriangleObject2, 3, 14)
   ProcessShape2(RectangleObject2, 3, 5)
End Sub

Sub ProcessShape2(ByVal Shape2 As Shape2, ByVal X As Double, _
      ByVal Y As Double)
   MessageBox.Show("The area of the object is " _
      & Shape2.CalculateArea(X, Y))
End Sub

Public Interface Shape2
   Function CalculateArea(ByVal X As Double, ByVal Y As Double) As Double
End Interface

Public Class RightTriangleClass2
   Implements Shape2
   Function CalculateArea(ByVal X As Double, _
         ByVal Y As Double) As Double Implements Shape2.CalculateArea
      ' Calculate the area of a right triangle.
      Return 0.5 * (X * Y)
   End Function
End Class

Public Class RectangleClass2
   Implements Shape2
   Function CalculateArea(ByVal X As Double, _
         ByVal Y As Double) As Double Implements Shape2.CalculateArea
      ' Calculate the area of a rectangle.
      Return X * Y
   End Function
End Class
```

Designing an Inheritance Hierarchy

Inheritance hierarchies are easier to implement than to design, which makes it risky to start coding before clearly identifying your needs. Correcting design mistakes in a class hierarchy after implementation can require code changes that disable existing applications. This section discusses inheritance hierarchy design considerations with an eye to avoiding such mistakes.

In This Section

Class Hierarchy Design Considerations for Extensibility
Discusses how to design class hierarchies so they can be updated or extended by other developers.
Considerations for Choosing Access Levels for Methods

Class Design Changes After Deployment
Explains issues that developers face when attempting to make changes to a class hierarchy.

Related Sections

When to Use Interfaces
Discusses when to use interfaces instead of an inheritance hierarchy.
Interfaces in Visual Basic .NET
Summarizes how to design and implement interfaces.

Class Hierarchy Design Considerations for Extensibility

Even well-designed class hierarchies need to evolve over time. The choices you make early on when designing a class hierarchy can simplify things later on.

The following list contains some suggestions for making your class hierarchies easier to extend:

- Class hierarchies are defined from the general to the specific. Define classes at each level of an inheritance hierarchy to be as general as possible. Derived classes inherit, and can reuse and extend methods from base classes.

  Suppose, for example, you are designing a class hierarchy that models computer hardware. When you start modeling output devices you could define classes named Display, Printer, and File. You could then define the classes that implement the methods defined in the base classes. For example, the LCDDisplay class could be derived from Display and implement a method named EnterPowerSaveMode.

- Be generous in defining data types and storage to avoid difficult changes later on. For example, you might consider using a variable of type **Long** even though your current data may only require a standard **Integer** variable.
- Only expose items that you are sure derived classes need. **Private** fields and methods reduce naming conflicts and prevent other users from using items that you may need to change down the road.
- Members that are only needed by derived classes should be marked as protected. This reduces the number of classes that are dependent on these members to just derived classes making it easier to update those members during development of the class.

See Also

MustInherit | MustOverride | Considerations for Choosing Access Levels for Methods | Class Design Changes After Deployment

Considerations for Choosing Access Levels for Methods

Applying the optimal access levels to members of a class hierarchy makes the hierarchy easier to maintain by allowing you to control how such members will be used.

As a rule, you should declare class members with access modifiers that provide the least amount of access feasible. Restricting access to class members reduces naming conflicts and prevents methods from being used in unintended ways.

Internal class members should be declared as **Private**; such members are only accessible from within the class in which they are defined.

Methods that are only used within a class or by descendants of a class should use the **Protected** access modifier. A **Protected** member is accessible within the class in which it is declared, and from within any class derived from the class that declared this member.

Friend data members can be accessed from outside a class but only by modules that are part of the project where the class is defined.

Public data members are visible to everyone and are often used at the bottom of a class hierarchy.

See Also

Class Hierarchy Design Considerations for Extensibility | Class Design Changes After Deployment

Class Design Changes After Deployment

Ideally, class hierarchies never change after deployment because even small changes risk unintended consequences. In the real world, such changes are sometimes unavoidable: product requirements can change, and design specifications sometimes omit key elements. One category of inheritance problems is called the *fragile base class problem*.

The Fragile Base Class Problem

The main drawback to using inheritance hierarchies is a problem called *fragile base classes*. Changes to base classes often require the base class and all the code in derived classes to be changed, recompiled, and redistributed. This problem is even more difficult when multiple developers author the base class and derived classes, because each party may deny access to their source code. In a worst-case scenario, a customer might inadvertently use the compiled binary form of an updated base class with the original and incompatible binary version of the derived classes.

Base class changes that can potentially break derived classes include overriding or changing the data type of base class members.

Minimizing Fragile Base Class Problems

The best way to avoid the fragile base class problem is to make changes only in derived classes. However, this not always possible because it requires you to consider every possibility when the base class is first released; despite one's best efforts, unforeseeable changes to the base class are sometimes inevitable.

Using **MustInherit** classes and **MustOverride** methods help reduce fragile base class problems because doing so moves implementation details to derived classes and reduces the need for base class changes. Again, however, this is not always possible, even with the best planning.

Shadowed data members in derived classes are also helpful, because they reduce naming conflicts with base class members.

The safest way to extend the functionality of a base class is to add new members. The only way that new members can break a base class is if the derived class uses the **Overloads** keyword to inherit methods from the base class and introduce new methods with the same name. This problem can be avoided by explicitly specifying in the derived class what base class methods you want to inherit from the base by redefining those methods and delegating to them.

In a sense, all base classes are fragile to some degree. In the final analysis, the fragile base class problem cannot be eliminated, but it can be minimized through careful design of class hierarchies that reduces the need for base class changes, and through thorough testing when such changes are unavoidable.

COM Interop

The Component Object Model (COM) allows an object to expose its functionality to other components and to host applications. Most of today's software includes COM objects. Although .NET assemblies are the best choice for new applications, you may at times need to employ COM objects. This section covers some of the issues associated with creating and using COM objects with Visual Basic .NET.

Describes the process of calling COM types through COM interop.
Exposing .NET Framework Components to COM
Describes the preparation and use of managed types from COM.
Applying Interop Attributes
Covers attributes you can use when interoperating with unmanaged code.

Introduction to COM Interop

The Component Object Model (COM) allows an object to expose its functionality to other components and to host applications. While COM objects have been fundamental to Windows programming for many years, applications designed for the common language runtime (CLR) used by the .NET Platform offer many advantages.

.NET Platform applications will eventually replace those developed with COM. Until then, you may need to use or create COM objects with Visual Studio .NET. Interoperability with COM, or *COM interop*, enables you to use existing COM objects while transitioning to the .NET Platform at your own pace.

Managed Code and Data

Code developed for the .NET Platform is referred to as *managed code*, and contains metadata that is used by the common language runtime (CLR). Data used by .NET applications is called *managed data* because the .NET runtime manages data-related tasks such as allocating and reclaiming memory, and type checking. By default, Visual Basic .NET uses managed code and data, but you can access the unmanaged code and data of COM objects using interop assemblies (described later in this topic).

Assemblies

An assembly is the primary building block of a .NET Framework application. It is a collection of functionality that is built, versioned, and deployed as a single implementation unit containing one or more files. Each assembly contains an assembly manifest.

Type Libraries and Assembly Manifests

Type libraries describe characteristics of COM objects, such as member names and data types. Assembly manifests perform the same function for .NET applications. They include information about:

- Assembly identity, version, culture, and digital signature
- Files that make up the assembly implementation
- Types and resources that make up the assembly, including those that are exported from it
- Compile-time dependencies on other assemblies
- Permissions required for the assembly to run properly

For more information on assemblies and assembly manifests, see Assemblies.

Importing and Exporting Type Libraries

Visual Studio .NET contains a utility, Tlbimp, that lets you import information from a type library into a .NET application. You can generate type libraries from assemblies by using the Tlbexp utility.

For information on Tlbimp and Tlbexp, see Type Library Importer (Tlbimp.exe) and Type Library Exporter (Tlbexp.exe).

Interop Assemblies

Interop assemblies are .NET assemblies that act as a bridge between managed and unmanaged code, mapping COM object members to equivalent .NET managed members. Interop assemblies created by Visual Basic .NET handle many of the details of working with COM objects, such as interoperability marshaling.

Interoperability Marshaling

All .NET applications share a set of common types that allow interoperability of objects, regardless of the programming language used. The parameters and return values of COM objects sometimes use data types that are different than those used in managed code. *Interoperability marshaling* is the process of packaging parameters and return values into equivalent data types as they move to and from COM objects. For more information, see Interop Marshaling Overview.

See Also

COM Interop | Walkthrough: Implementing Inheritance with COM Objects | Interoperating with Unmanaged Code | Troubleshooting Interoperability | Assemblies | Type Library Importer (Tlbimp.exe) | Type Library Exporter (Tlbexp.exe) | Interop Marshaling Overview

Referencing COM Objects from Visual Basic .NET

In Visual Basic .NET, adding references to COM objects that have type libraries is similar to doing so in previous versions of Visual Basic. However, Visual Basic .NET adds the creation of an interop assembly to the procedure. References to the members of the COM object are routed to the interop assembly and then forwarded to the actual COM object. Responses from the COM object are routed to the interop assembly and forwarded to your .NET application.

To add references to COM objects

1. On the **Project** menu, select **Add Reference** and then click the **COM** tab.
2. Select the component you want to use from the list of COM objects.
3. To simplify access to the interop assembly, add an **Imports** statement to the top of the class or module in which you will use the COM object.

Manually Creating Interop Assemblies Using Tlbimp

Visual Basic .NET automatically creates interop assemblies when you add a reference to a type library from the integrated development environment (IDE). When working from the command line, you can use the Tlbimp utility to manually create interop assemblies.

To create an interop assembly using Tlbimp

1. Add the location of Tlbimp to the DOS search path, if it is not already part of the search path and you are not currently in the directory where it is located.
2. Call Tlbimp from a DOS prompt, providing the following information:
   - Name and location of the DLL that contains the type library
   - Name and location of the namespace where the information should be placed
   - Name and location of the target interop assembly

The following code provides an example:

```
Tlbimp test3.dll /out:NameSpace1 /out:Interop1.dll
```

You can use Tlbimp to create interop assemblies for type libraries, even for unregistered COM objects. However, the COM objects referred to via interop assemblies must be properly registered on the computer where they are to be used. You can register a COM object by using the Regsvr32 utility included with the Windows operating system.

COM Interop | Type Library Importer (Tlbimp.exe) | Type Library Exporter (Tlbexp.exe) |
Walkthrough: Implementing Inheritance with COM Objects | Troubleshooting Interoperability | Imports Statement

Working with ActiveX Controls

ActiveX controls are COM components or objects you can insert into a Web page or other application to reuse packaged functionality someone else programmed. You can use ActiveX controls developed for previous versions of Visual Basic to add features to the toolbox of Visual Studio .NET.

To add ActiveX controls to the toolbox

1. On the **Tools** menu, select **Add/Remove Toolbox Items**. The **Customize Toolbox** dialog is displayed.
2. Click the **COM Components** tab.
3. Select the check box next to the ActiveX control you want to use, and then click **OK**. The new control appears with the other tools in the toolbox.

> **Note** You can use the Aximp utility to manually create an interop assembly for ActiveX controls. For details, see Windows Forms ActiveX Control Importer (Aximp.exe).

Walkthrough: Calling Windows APIs

Windows APIs are dynamic link libraries (DLLs) that are part of the Windows operating system. You use them to perform tasks when it is difficult to write equivalent procedures of your own. For example, Windows provides a function named `FlashWindowEx` that lets you make the title bar for an application alternate between light and dark shades.

The advantage of using Windows APIs in your code is that they can save development time because they contain dozens of useful functions that are already written and waiting to be used. The disadvantage is that Windows APIs can be difficult to work with and unforgiving when things go wrong.

Windows dynamic-link libraries (DLLs) represent a special category of interoperability. Windows APIs do not use managed code, do not have built-in type libraries, and use data types that are different than those used with Visual Studio .NET. Because of these differences, and because Windows APIs are not COM objects, interoperability with Windows APIs and the .NET Platform is performed using platform invoke, or PInvoke. Platform invoke is a service that enables managed code to call unmanaged functions implemented in DLLs. For more information, see Consuming Unmanaged DLL Functions. You can use PInvoke in Visual Basic .NET by using either the **Declare** statement or applying the **DllImport** attribute to an empty procedure.

Windows API calls were an important part of Visual Basic programming in the past, but are seldom necessary with Visual Basic .NET. Whenever possible, you should use managed code from the .NET Framework to perform tasks instead of Windows API calls. This walkthrough provides information for those situations in which using Windows APIs is unavoidable.

API Calls Using Declare

The most common way to call Windows APIs is via the **Declare** statement.

To declare a DLL procedure

1. Determine the name of the function you want to call plus its arguments, argument types, and return value, as well as the name and location of the DLL that contains it.

   > **Note** For complete information about the Windows APIs, see the Win32 SDK documentation in the Platform SDK Windows API. For more information about the constants that Windows APIs use, examine the header files such as Windows.h included with the Platform SDK.

2. Open a new Windows Application project by clicking **New** on the **File** menu, and then clicking **Project**. The **New Project** dialog box appears.
3. Select **Windows Application** from the list of Visual Basic project templates. The new project is displayed.
4. Add the following **Declare** function either to the declaration section of the startup form for your project, or to the declaration section of the class or module where you want to use the DLL:

```
Declare Auto Function MBox Lib "user32.dll" _
Alias "MessageBox" (ByVal hWnd As Integer, _
   ByVal txt As String, ByVal caption As String, _
   ByVal Typ As Integer) As Integer
```

Parts of the Declare Statement

The **Declare** statement includes the following elements.

Auto modifier

The **Auto** modifier instructs the runtime to convert the string based on the method name according to common language runtime rules (or alias name if specified).

Lib and Alias keywords

The name following the **Function** keyword is the name your program uses to access the imported function. It can be the same as the real name of the function you are calling, or you can use any valid procedure name and then employ the **Alias** keyword to specify the real name of the function you are calling.

Specify the **Lib** keyword followed by the name and location of the DLL that contains the function you are calling. You do not need to specify the path for files located in the windows system directories.

Use the **Alias** keyword if the name of the function you are calling is not a valid Visual Basic procedure name, or conflicts with the name of other items in your application. **Alias** indicates the true name of the function being called.

Argument and Data Type Declarations

Declare the arguments and their data types. This part can be challenging because the data types that Windows uses do not correspond to Visual Studio data types. Visual Basic does a lot of the work for you by converting arguments to compatible data types, a process called *marshaling*. You can explicitly control how arguments are marshaled by using the **MarshalAs** attribute defined in the **System.Runtime.InteropServices** namespace.

> **Note** Previous versions of Visual Basic allowed you to declare parameters **As Any**, meaning that data of any data type could be used. Visual Basic .NET requires that you use a specific data type for all declare statements.

Windows API Constants

Some arguments are combinations of constants. For example, the **MessageBox** API shown in this walkthrough accepts an integer argument called `Typ` that controls how the message box is displayed. You can determine the numeric value of these constants by examining the **#define** statements in the file WinUser.h. The numeric values generally are shown in hexadecimal, so you may want to use a calculator to add them and convert to decimal. For example, if you want to combine the constants for the exclamation style **MB_ICONEXCLAMATION** 0x00000030 and the Yes/No style **MB_YESNO** 0x00000004, you can add the numbers and get a result of 0x00000034, or 52 decimal. Although you can use the decimal result directly, it is better to declare these values as constants in your application and combine them using the **Or** operator.

To declare constants for Windows API calls

1. Consult the documentation for the Windows function you are calling and determine the name the constants it uses, and the name of the .h file that contains the numeric values for these constants.
2. Use a text editor, such as Notepad, to view the contents of the .h file and find the values associated with the constants you are using. For example, the **MessageBox** API uses the constant **MB_ICONQUESTION** to show a question mark in the message box. The definition for MB_ICONQUESTION is in WinUser.h and appears as follows:

```
#define MB_ICONQUESTION             0x00000020L
```

3. Add equivalent **Const** statements to the declarations section of your class or module to make these constants available to your application. For example:

```
Const MB_ICONQUESTION = &H20L
Const MB_YESNO = &H4
Const IDYES = 6
Const IDNO = 7
```

To call the DLL procedure

1. Add a button named `Button1` to the startup form for your project, and then double-click it to view its code. The event handler for the button is displayed.
2. Add code to the **Click** event handler for the button you added to call the procedure, and provide the appropriate arguments:

```
Private Sub Button1_Click(ByVal sender As System.Object, _
                          ByVal e As System.EventArgs) _
                          Handles Button1.Click
   Dim RetVal As Integer ' Stores the return value.
   RetVal = MBox(0, "Declare DLL Test", "Windows API MessageBox", _
                 MB_ICONQUESTION Or MB_YESNO)
' Check the return value.
   If RetVal = IDYES Then
      MsgBox("You chose Yes")
   Else
      MsgBox("You chose No")
   End If
End Sub
```

3. Run the project by pressing F5. The message box is displayed with both **Yes** and **No** response buttons. Click either one.

Data Marshaling

Visual Basic .NET automatically converts the data types of parameters and return values for Windows API calls, but you can use the **MarshalAs** attribute to explicitly specify unmanaged data types that an API expects. For more information about interop marshaling, see Interop Marshaling

To use Declare and MarshalAs in an API call

1. Determine the name of the function you want to call, plus its arguments, data types, and return value.
2. To simplify access to the **MarshalAs** attribute, add an **Imports** statement to the top of the code for the class or module, as in the following example:

```
Imports System.Runtime.InteropServices
```

3. Add a function prototype for the imported function to the declarations section of the class or module you are using, and apply the **MarshalAs** attribute to the parameters or return value. In the following example, an API call that expects the type **Void*** is marshaled as **UnmanagedType.AsAny**:

```
Declare Sub SetData Lib "..\LIB\UnmgdLib.dll" (ByVal x As Short, _
      <MarshalAsAttribute(UnmanagedType.AsAny)> ByVal o As Object)
```

API Calls Using DllImport

The **DllImport** attribute provides a second way to call functions in DLLs without type libraries. **DllImport** is roughly equivalent to using a **Declare** statement but provides more control over how functions are called.

You can use **DllImport** with most Windows API calls as long as the call refers to a shared (sometimes called *static*) method. You cannot use methods that require an instance of a class. Unlike **Declare** statements, **DllImport** calls cannot use the **MarshalAs** attribute.

To call a Windows API using the DllImport attribute

1. Open a new Windows Application project by clicking **New** on the **File** menu, and then clicking **Project**. The **New Project** dialog box appears.
2. Select **Windows Application** from the list of Visual Basic project templates. The new project is displayed.
3. Add a button named `Button2` to the startup form.
4. Double-click `Button2` to open the code view for the form.
5. To simplify access to **DllImport**, add an **Imports** statement to the top of the code for the startup form class:

```
Imports System.Runtime.InteropServices
```

6. Declare an empty function preceding the **End Class** statement for the form, and name the function `MoveFile`.
7. Apply the **Public** and **Shared** modifiers to the function declaration and set parameters for `MoveFile` based on the arguments the Windows API function uses:

```
Public Shared Function _
MoveFile(ByVal src As String, ByVal dst As String) As Boolean
   ' Leave the body of the function empty.
End Sub
```

   Your function can have any valid procedure name; the **DllImport** attribute specifies the name in the DLL. It also handles interoperability marshaling for the parameters and return values, so you can choose Visual Studio .NET data types that are similar to the data types the API uses.

8. Apply the **DllImport** attribute to the empty function. The first parameter is the name and location of the DLL containing the function you are calling. You do not need to specify the path for files located in the Windows system directories. The second parameter is a named argument that specifies the name of the function in the Windows API:

```
<DllImport("KERNEL32.DLL", EntryPoint:="MoveFileW", SetLastError:=True, _
```

```
CharSet:=CharSet.Unicode, ExactSpelling:=True, _
CallingConvention:=CallingConvention.StdCall)> _
Public Shared Function _
MoveFile(ByVal src As String, ByVal dst As String) As Boolean
   ' This function copies a file from the path src to the path dst.
   ' Leave function empty - DllImport attribute forces calls
   ' to MoveFile to be forwarded to MoveFileW in KERNEL32.DLL.
End Function
```

9. Add code to the **Button2_Click** event handler to call the function:

```
Private Sub Button2_Click(ByVal sender As System.Object, _
                          ByVal e As System.EventArgs) _
                          Handles Button2.Click
   Dim RetVal As Boolean
   RetVal = MoveFile("c:\tmp\Test.txt", "c:\Test.txt")
   If RetVal = True Then
      MsgBox("The file was moved successfully.")
   Else
      MsgBox("The file could not be moved.")
   End If
End Sub
```

10. Create a file named Test.Txt and place it in the C:\Tmp directory on your hard drive. Create the Tmp directory if necessary.
11. Press F5 to start the application. The main form appears.
12. Click `Button2`. The message "The file was moved successfully" is displayed if the file can be moved.

Walkthrough: Creating COM Objects with Visual Basic .NET

Although .NET assemblies are the best choice for new applications, you may at times need to employ COM objects instead. This walkthrough demonstrates two ways to create COM objects with Visual Basic .NET: with and without the COM class template.

The easiest way to create COM objects is by using the COM class template. The COM class template creates a new class, then configures your project to generate the class as a COM object and register it with the operating system.

To create a COM object using the COM class template

1. Open a new Windows Application project by clicking **New** on the **File** menu, and then clicking **Project**. The **New Project** dialog box appears.
2. With **Visual Basic Projects** highlighted in the **Project Types** list, select **Class Library** from the **Templates** list, and then click **OK**. The new project is displayed.
3. Select **Add New Item** from the **Project** menu. The **Add New Item** dialog box is displayed.
4. Select **COM Class** from the **Templates** list, and then click **Open**. Visual Basic .NET adds a new class and configures the new project for COM interop.
5. Add code, such as properties, methods, and events to the COM class.
6. Select **Build Solution** from the **Build** menu. Visual Basic .NET builds the assembly and registers the COM object with the operating system.

Creating COM Objects Without the COM Class Template

You can create a COM class manually instead of using the COM class template. This procedure can be helpful when working from the command line or when you want more control over how COM objects are defined.

To set up your project to generate a COM object

1. Open a new Windows Application project by clicking **New** on the **File** menu, and then clicking **Project**. The **New Project** dialog box appears.
2. With **Visual Basic Projects** highlighted in the **Project Types** list, select **Class Library** from the **Templates** list, and then click **OK**. The new project is displayed.
3. In the Solution Explorer, right-click your project, and then click **Properties**. The **Property Pages** dialog box is displayed.
4. Click the **Configuration Properties** folder, and then click the **Build** folder. The **Build** properties are displayed.
5. Check the **Register for COM Interop** check box.

To set up the code in your class to create a COM object

1. In the Solution Explorer, double-click Class1.vb to display its code.
2. Rename the class.
3. Add the **ComClass** attribute to the class, specifying the guids for the Class ID, Interface ID, and events Events ID as in the following example:

```
<ComClass(ComClass1.ClassId, ComClass1.InterfaceId, ComClass1.EventsId)> _
Public Class ComClass1
```

4. Supply the Globally Unique Identifier (GUID) constants for the **ComClass** attribute. To create GUIDs for your COM object, click **Create GUID** on the **Tools** menu, or launch guidgen.exe to start the guidgen utility. Select **Registry Format** from the list of formats provided by the guidgen application. Click the **New GUID** button to generate the GUID and click the **Copy** button to copy the GUID to the clipboard. Paste the GUID into the Visual Studio .Net code editor. Remove the leading and trailing braces from the GUID provided. For example, if the GUID provided by guidgen is `"{2C8B0AEE-02C9-486e-B809-C780A11530FE}"` then the GUID should appear as: `"2C8B0AEE-02C9-486e-B809-C780A11530FE"`.
5. Click the **New GUID** and **Copy** buttons until you have generated GUIDS for the ClassId, InterfaceId, and EventsId. For example:

```
Public Const ClassId As String = "832F34A5-5CF5-403f-B4A8-428C8351FD02"
Public Const InterfaceId As String = "3D8B5BA4-FB8C-5ff8-8468-11BF6BD5CF91"
Public Const EventsId As String = "2B691787-6ED7-401e-90A4-B3B9C0360E31"
```

6. COM classes must have a parameterless `Public Sub New()` constructor, or the class will not register correctly. Add a

parameterless constructor to the class:

```
Public Sub New()
   MyBase.New()
End Sub
```

7. Add properties, methods and events to the class, ending it with an **End Class** statement. Select **Build Solution** from the **Build** menu. Visual Basic .NET builds the assembly and registers the COM object with the operating system.

   Note The COM objects you generate with Visual Studio .NET cannot be used by other Visual Studio .NET applications. Attempts to add references to such COM objects raise an error.

COM Interop | ComClassAttribute Class | Walkthrough: Implementing Inheritance with COM Objects | #Region Directive

Troubleshooting Interoperability

When interoperating between COM and the managed code of the .NET platform, you may encounter one or more of the following common issues.

Interop Marshaling

Exporting Fixed-Length Strings to Unmanaged Code

Exporting Inheritance Hierarchies

Use of COM Objects Through Interop Assemblies

Classes Exposed as Both Interfaces and Classes

Creating Instances of a .NET Class

Data Types for Parameters and Return Values

Module level COM Methods

Unhandled Errors in Event Handlers

ActiveX Control Issues

Passing ReadOnly Properties of Controls ByRef

Deploying Assemblies That Expose Interop

Interop Marshaling

At times, you may need to use data types that are not part of the .NET Framework. Interop assemblies handle most of the work for COM objects, but you may need to control the data types used when managed objects are exposed to COM. For example, structures in class libraries must specify the **BStr** unmanaged type on strings sent to COM objects created by previous versions of Visual Basic. In such cases, you can use the **MarshalAs** attribute to cause managed types to be exposed as unmanaged types.

Exporting Fixed-Length Strings to Unmanaged Code

In previous versions of Visual Basic, strings are exported to COM objects as sequences of bytes without a null termination character. For compatibility with other languages, Visual Basic .NET includes a termination character when exporting strings. The best way to address this incompatibility is to export strings lacking the termination character as arrays of **Byte** or **Char**.

Exporting Inheritance Hierarchies

Managed class hierarchies flatten out when exposed as COM objects. For example, if you define a base class with a member, and then inherit the base class in a derived class that is exposed as a COM object, clients that use the derived class in the COM object will not be able to use the inherited members. Base class members are accessible from COM objects only as instances of a base class, and then only if the base class is also created as a COM object.

Use of COM Objects Through Interop Assemblies

You use interop assemblies almost as though they are managed code replacements for the COM objects they represent. However, because they are wrappers and not actual COM objects, there are some differences between using interop assemblies and standard assemblies. These areas of difference include the exposure of classes, and data types for parameters and return values.

Classes Exposed as Both Interfaces and Classes

Unlike classes in standard assemblies, COM classes are exposed in interop assemblies as both an interface and a class that represents the COM class. The interface's name is identical to that of the COM class. The name of the interop class is the same as that of the original COM class, but with the word "Class" appended. For example, suppose you have a project with a reference to an interop assembly for a COM object. If the COM class is named `MyComClass`, IntelliSense and the Object Browser show an interface named `MyComClass` and a class named `MyComClassClass`.

Creating Instances of a .NET Class

Generally, you create an instance of a .NET class using the **New** statement with a class name. Having a COM class represented by an interop assembly is the one case in which you can use the **New** statement with an interface. Unless you are using the COM class with an **Inherits** statement, you can use the interface the same way as you would a class, as in the following code:

```
Dim Class1 As New MyComClass()
```

However, if you are using the COM class as the base for a derived class, you must use the interop class that represents the COM class, as in the following code:

```
Class DerivedClass
   Inherits MyComClass.AddClassClass
End Class
```

> **Note** Interop assemblies implicitly implement interfaces that represent COM classes. You should not attempt to use the implements statement to implement these interfaces or an error will result.

Data Types for Parameters and Return Values

Unlike members of standard assemblies, interop assembly members may have data types that are different than those used in the object's original declaration. Although interop assemblies implicitly convert COM types to compatible common language runtime types, you should pay attention to the data types used by both sides to prevent runtime errors. For example, in COM objects created with Visual Basic 6.0, values of type **Integer** assume the .NET equivalent type, **Short**. It is recommended that you use the Object Browser to examine the characteristics of imported members before using them.

Module level COM methods

Most COM objects are used by creating an instance of a COM class using the **New** keyword and then calling methods of the object. One exception to this rule involves COM objects that contain "AppObj" or "GlobalMultiUse" COM classes. Such classes are similar to module level methods in Visual Basic .NET classes. Visual Basic 6.0 implicitly creates instances of such objects for you the first time you call one of their methods. For example, in Visual Basic 6.0 you can add a reference to the **Microsoft DAO 3.6 Object Library** and call the `DBEngine` method without first creating an instance:

```
Dim db As DAO.Database
' Open the database
Set db = DBEngine.OpenDatabase("C:\nwind.mdb")
' Use the database object
```

Visual Basic .NET requires that you always create instances of COM objects before you can use their methods. To use these methods in Visual Basic .NET, declare a variable of the desired class and use the new keyword to assign the object to the object variable. The **Shared** keyword can be used when you want to make sure that only one instance of the class is created.

```
' Declarations level variable.
Shared DBEngine As New DAO.DBEngine()

   Sub DAOOpenRecordset()
      Dim db As DAO.Database
      Dim rst As DAO.Recordset
      Dim fld As DAO.Field
      ' Open the database
      db = DBEngine.OpenDatabase("C:\nwind.mdb")

      ' Open the Recordset
      rst = db.OpenRecordset _
        ("SELECT * FROM Customers WHERE Region = 'WA'", _
         DAO.RecordsetTypeEnum.dbOpenForwardOnly, _
         DAO.RecordsetOptionEnum.dbReadOnly)
      ' Print the values for the fields in the debug window.
      For Each fld In rst.Fields
         Debug.WriteLine(fld.Value & ";")
      Next
      Debug.WriteLine("")
      ' Close the recordset
      rst.Close()
   End Sub
```

Unhandled Errors in Event Handlers

One common interop problem involves errors in event handlers that handle events raised by COM objects. Such errors are ignored unless you specifically check for errors using **On Error** or **Try...Catch...Finally** statements. For example, the following example is from a Visual Basic .NET project that has a reference to the ADODB COM object.

```
' To use this example, add a reference to ADODB from the
' COM tab of the project references page.
Dim WithEvents cn As New ADODB.Connection()
Sub ADODBConnect()
   cn.ConnectionString = _
   "Provider=Microsoft.Jet.OLEDB.4.0;" & _
   "Data Source=C:\NWIND.MDB"
   cn.Open()
   MsgBox(cn.ConnectionString)
End Sub

Private Sub Form1_Load(ByVal sender As System.Object, _
                       ByVal e As System.EventArgs) Handles MyBase.Load
   ADODBConnect()
End Sub

Private Sub cn_ConnectComplete(ByVal pError As ADODB.Error, _
                               ByRef adStatus As ADODB.EventStatusEnum, _
                               ByVal pConnection As ADODB.Connection) _
                               Handles cn.ConnectComplete
'  This is the event handler for the cn_ConnectComplete event raised
'  by the ADODB.Connection object when a database is opened.
   Dim x As Integer = 6
   Dim y As Integer = 0
   Try
      x = x / y ' Attempt to divide by zero.
      ' This procedure would fail silently without exception handling.
   Catch ex As Exception
      MsgBox("There was an error: " & ex.Message)
   End Try
End Sub
```

This example raises an error as expected. However, if you try the same example without the **Try...Catch...Finally** block, the error is ignored as if you used the **OnError Resume Next** statement. Without error handling, the division by zero silently fails. Because such errors never raise unhandled exception errors, it is vital that you use some form of exception handling in event handlers that handle events from COM objects.

Understanding COM interop errors

Without error handling, interop calls often generate errors that provide little information. Whenever possible, use structured error handling to provide more information about problems when they occur. This can be particularly helpful when debugging applications For example:

```
Try
' Place call to COM object here.
Catch ex As Exception
' Display information about the failed call.
End Try
```

You can find out information such as the error description, HRESULT, and the source of COM errors by examining the contents of the exception object.

ActiveX Control Issues

Most ActiveX controls that work with Visual Basic 6.0 work with Visual Basic .NET without trouble. The main exceptions are container controls, or controls that visually contain other controls. Some examples of older controls that do not work correctly with Visual Studio .NET are:

- Microsoft Forms 2.0 Frame control
- Up-Down control, also known as the spin control

- Sheridan Tab Control

There are only a few workarounds for unsupported ActiveX control problems. You can migrate existing controls to Visual Studio .NET if you own the original source code. Otherwise, you can check with software vendors for updated .NET compatible versions of controls to replace unsupported ActiveX controls.

Passing ReadOnly Properties of Controls ByRef

Visual Basic .NET sometimes raises COM errors such as "**Error 0x800A017F CTL_E_SETNOTSUPPORTED**" when you to pass **ReadOnly** properties of some older ActiveX controls as **ByRef** parameters to other procedures. Similar procedure calls from Visual Basic 6.0 do not raise an error, and the parameters are treated as if you passed them by value. The error message you see in Visual Basic .NET is the COM object reporting that you are attempting to change a property that does not have a property **Set** procedure.

If you have access to the procedure being called, you can prevent this error by using the **ByVal** keyword to declare parameters that accept **ReadOnly** properties. For example:

```
Sub ProcessParams(ByVal c As Object)
   'Use the arguments here.
End Sub
```

If you do not have access to the source code for the procedure being called, you can force the property to be passed by value by adding an extra set of brackets around the calling procedure. For example:

```
Sub PassByVal ()
' The extra set of parens around the arguments
' forces them to be passed by value.
   ProcessParams((Me.AxListView1.ListItems))
End Sub
```

Deploying Assemblies That Expose Interop

Deploying assemblies that expose COM interfaces presents some unique challenges. For example, a potential problem arises when separate applications reference the same COM assembly. This situation is common when a new version of an assembly is installed and another application is still using the old version of the assembly. Uninstalling any assembly that shares a dll can unintentionally make it unavailable to the other assemblies.

To avoid this problem, you should install shared assemblies to the Global Assembly Cache (GAC) and use a MergeModule for the component. If you are unable to install the application in the GAC, then it should be installed to CommonFilesFolder in a version-specific subdirectory.

Assemblies that are not shared should be placed side by side in the directory with the calling application.

Multithreading in Visual Basic .NET

Visual Basic .NET applications can perform multiple tasks simultaneously using *multithreading* (or *free threading*), a process in which individual tasks execute on separate threads. Multithreading improves the performance and responsiveness of your applications.

Shows how to create multithreaded components.

Multithreaded Applications

With Visual Basic .NET, you can write applications that perform multiple tasks simultaneously. Tasks with the potential of holding up other tasks can execute on separate threads, a process known as *multithreading* or *free threading*. Applications that use multithreading are more responsive to user input because the user interface stays active while processor-intensive tasks execute on separate threads. Multithreading is also useful when creating scalable applications, because you can add threads as the workload increases.

Creating and Using Threads

You create a new thread in Visual Basic .NET by declaring a variable of type **System.Threading.Thread** and calling the constructor with the **AddressOf** statement and the name of the procedure or method you want to execute on the new thread. The following code provides an example:

```
Dim MyThread As New System.Threading.Thread(AddressOf MySub)
```

Starting and Stopping Threads

To start the execution of a new thread, use the **Start** method, as in the following code:

```
MyThread.Start()
```

To stop the execution of a thread, use the **Abort** method, as in the following code:

```
MyThread.Abort()
```

Besides starting and stopping threads, you can also pause threads by calling the **Sleep** or **Suspend** methods, resume a suspended thread with the **Resume** method, and destroy a thread using the **Abort** method, as in the following code:

```
MyThread.Sleep ()
MyThread.Suspend ()
MyThread.Abort ()
```

The following table shows some of the methods you can use to control individual threads.

Method	Action
Start	Causes a thread to start running.
Sleep	Pauses a thread for a specified time.
Suspend	Pauses a thread when it reaches a safe point.
Abort	Stops a thread when it reaches a safe point.
Resume	Restarts a suspended thread
Join	Causes the current thread to wait for another thread to finish. If used with a timeout value, this method ret urns **True** if the thread finishes in the allotted time.

Most of these methods are self explanatory, but the concept of *safe points* may be new to you. Safe points are places in code where it is safe for the common language runtime to perform automatic *garbage collection*, the process of releasing unused variables and reclaiming memory. When you call the **Abort** or **Suspend** methods of a thread, the common language runtime analyzes the code and determines the location of an appropriate place for the thread to stop running.

Threads also contain a number of useful properties, as shown in the following table:

Property	Value
thread.IsAlive	Contains the value **True** if a thread is active.
IsBackground	Gets or sets a Boolean that indicates if a thread is or should be a background thread. Background t hreads are like foreground threads, but background threads do not prevent a process from termin ating. Once all foreground threads belonging to a process have terminated, the common languag e runtime ends the process by calling the **Abort** method on background threads that are still alive.
Name	Gets or sets the name of a thread. Most commonly used to discover individual threads when debu gging.

Priority	Gets or sets a value used by the operating system to prioritize thread scheduling.
ApartmentState	Gets or sets the threading model used for a particular thread. Threading models are important wh en a thread calls unmanaged code.
ThreadState	Contains a value that describes a thread's state or states.

See Thread States for more information on thread states and methods.

Thread Priorities

Every thread has a priority property — that determines how large of a time slice it gets to execute. The operating system allocates longer time slices to high-priority threads than it does to low-priority threads. New threads are created with the value of **Normal**, but you can adjust the **Priority** property to any of the other values in the **System.Threading.ThreadPriority** enumeration.

See ThreadPriority Enumeration for a detailed description of the various thread priorities.

Foreground and Background Threads

A *foreground thread* runs indefinitely, while a *background thread* terminates once the last foreground thread has stopped. You can use the **IsBackground** property to determine or change the background status of a thread.

Thread States | Parameters and Return Values for Multithreaded Procedures | Thread Synchronization | Multithreading with Forms and Controls | Multithreading in Components

Thread States

The **ThreadState** property provides information about the status of a thread. Because threads can be in more than one state at any given time, the value stored in **ThreadState** can be a combination of the values in the **System.Threading.Threadstate** enumeration. For example, if a thread is blocked on a call to **System.Threading.Monitor.Wait**, and another thread calls the **Abort** method on that same thread, the thread is in both the **Waiting** and the **AbortRequested** state at the same time.

Changing Thread States

Once a thread has started, you can call its methods to change its state. For example, you can cause a thread to pause for a fixed number of milliseconds by calling **Thread.Sleep**. The **Sleep** method takes as a parameter a timeout, which is the number of milliseconds that the thread remains blocked. Calling **Thread.Sleep(System.Threading.Timeout.Infinite)** causes a thread to sleep until it is interrupted by another thread that calls **Thread.Interrupt**. The **Thread.Interrupt** method wakes the destination thread out of any wait it may be in and causes an exception to be raised.

You can also pause a thread by calling **Thread.Suspend**. When a thread calls **Thread.Suspend** on itself, the call blocks until another thread resumes it by calling **Thread.Resume**. When a thread calls **Thread.Suspend** on another thread, the call is non-blocking and causes the other thread to pause. Calling **Thread.Resume** breaks another thread out of its suspended state and causes it to resume execution. Unlike **Thread.Sleep**, **Thread.Suspend** does not immediately stop a thread; the suspended thread does not pause until the common language runtime determines that it has reached a safe point.

The **Thread.Abort** method stops a running thread by raising a **ThreadAbortException** exception that causes the thread to die.

See Thread Methods for detailed information about these methods.

Parameters and Return Values for Multithreaded Procedures

Supplying and returning values in a multithreaded applications is complicated because the constructor for the thread class must be passed a reference to a procedure that takes no arguments and returns no value. The following sections show some simple ways to supply parameters and return values from procedures on separate threads.

Supplying Parameters for Multithreaded Procedures

The best way to supply parameters for a multithreaded method call is to wrap the target method in a class and define fields for that class that will serve as parameters for the new thread. The advantage of this approach is that you can create a new instance of the class, with its own parameters, every time you want to start a new thread. For example, suppose you have a function that calculates the area of a triangle, as in the following code:

```
Function CalcArea(Base As Double, Height As Double) As Double
   CalcArea= 0.5 * Base * Height
End Sub
```

You can write a class that wraps the `CalcArea` function and creates fields to store input parameters, as follows:

```
Class AreaClass
    Public Base As Double
    Public Height As Double
    Public Area As Double
    Sub CalcArea()
        Area = 0.5 * Base * Height
        MsgBox("The area is: " & Area)
    End Sub
End Class
```

To use the `AreaClass`, you can create an `AreaClass` object, and set the `Base` and `Height` properties as shown in the following code:

```
Protected Sub TestArea()
   Dim AreaObject As New AreaClass()
   Dim Thread As New System.Threading.Thread _
                   (AddressOf AreaObject.CalcArea)
   AreaObject.Base = 30
   AreaObject.Height = 40
   Thread.Start()
End Sub
```

Notice that the `TestArea` procedure does not check the value of the `Area` field after calling the `CalcArea` method. Because `CalcArea` runs on a separate thread, the `Area` field is not guaranteed to be set if you check it immediately after calling `Thread.Start`. The next section discusses a better way to return values from multithreaded procedures.

Returning Values From Multithreaded Procedures

Returning values from procedures that run on separate threads is complicated by the fact that the procedures cannot be functions and cannot use **ByRef** arguments. The best way to return values is to have your multithreaded procedure call a procedure in your application, and then pass the results as arguments. To do this, raise an event when a task is done, and process the results with an event handler.

The following example returns a value by raising an event from a procedure running on a separate thread:

```
Class AreaClass2
    Public Base As Double
    Public Height As Double
    Private Area As Double
    Public Event ThreadDone(ByVal Area As Double)
    Sub CalcArea()
        Area = 0.5 * Base * Height  ' Calculate the area of a triangle.
        RaiseEvent ThreadDone(Area) ' Raise an event to return the area.
    End Sub
```

```
End Class

Dim WithEvents AreaObject2 As AreaClass2
Protected Sub TestArea2()
   AreaObject2 = New AreaClass2()
   Dim Thread As New System.Threading.Thread _
                           (AddressOf AreaObject2.CalcArea)
   AreaObject2.Base = 30
   AreaObject2.Height = 40
   Thread.Start()
End Sub

Sub AreaDoneEventHandler(ByVal Area As Double) _
                         Handles AreaObject2.ThreadDone
   MsgBox("The area is: " & Area)
End Sub
```

You can provide parameters and return values to thread pool threads by using the optional **ByVal** state object variable of the **QueueUserWorkItem** method. Thread timer threads also support a state object for this purpose. For information on the thread pooling and thread timers, see Thread Pooling and Thread Timers.

Thread Synchronization

As you write a threaded application, you may need to synchronize individual threads with other parts of your program. Synchronization provides a compromise between the unstructured nature of multithreaded programming and the structured order of synchronous processing.

You use synchronization techniques:

- To explicitly control the order in which code runs whenever tasks must be performed in a specific sequence

  -or-

- To prevent the problems that can occur when two threads share the same resource at the same time.

For example, you could use synchronization to cause a display procedure to wait until a data retrieval procedure that is running on another thread is complete.

Using events is a common way to synchronize threaded applications. In this scenario, each thread raises an event to signal its status to the main program or other threads. Other parts of the application, outside the thread that raised the event, handle the event and process the information.

> **Note** When an event is raised from one object to another object, the event handler will execute on the same thread that the **RaiseEvent** occurred. Therefore, if the event handler accesses shared data it must itself use synchronization if that data may be simultaneously accessed on a different thread

Although using events is a simple way to synchronize threads, there are limitations to this approach. Visual Basic .NET includes other features for controlling individual threads and their access to specific sections of code. The following sections discuss synchronization techniques.

Synchronization Techniques

There are two approaches to synchronization, polling and using synchronization objects. Polling repeatedly checks the status of an asynchronous call from within a loop. Polling is the least efficient way to manage threads because it wastes resources by repeatedly checking the status of the various thread properties.

For example, the **IsAlive** property can be used when polling to see if a thread has exited. Use this property with caution because a thread that is alive is not necessarily running. You can use the thread's **ThreadState** property to get more detailed information about a thread's status. Because threads can be in more than one state at any given time, the value stored in **ThreadState** can be a combination of the values in the **System.Threading.Threadstate** enumeration. Consequently, you should carefully check all relevant thread states when polling. For example, if a thread's state indicates that it is not **Running,** it may be done. On the other hand, it may be suspended or sleeping.

Waiting for a Thread to Finish

The **Thread.Join** method is useful for determining if a thread has completed before starting another task. The **Join** method waits a specified amount of time for a thread to end. If the thread ends before the timeout, **Join** returns **True;** otherwise it returns **False**. For information on **Join**, see Thread.Join Method

As you can imagine, polling sacrifices many of the advantages of multithreading in return for control over the order that threads run. Because it is so inefficient, polling generally not recommended. A more efficient approach would use the **Join** method to control threads. **Join** causes a calling procedure to wait either until a thread is done or until the call times out if a timeout is specified. The name, join, is based on the idea that creating a new thread is a fork in the execution path. You use **Join** to merge separate execution paths into a single thread again.

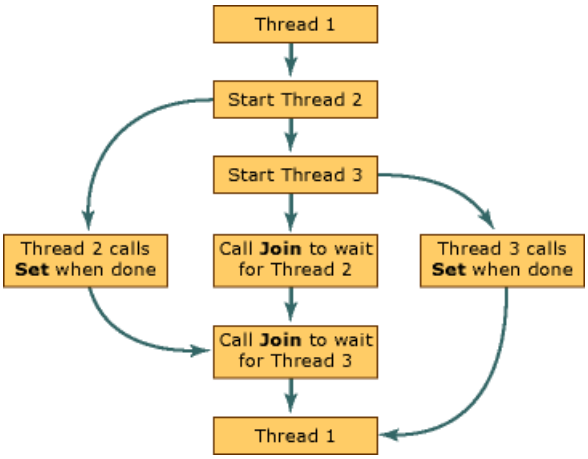

Figure 1 Threading

One point should be clear: **Join** is a synchronous or *blocking* call. Once you call Join or a wait method of a wait handle, the calling procedure stops and waits for the thread to signal that it is done.

```
Sub JoinThreads()
   Dim Thread1 As New System.Threading.Thread(AddressOf SomeTask)
   Thread1.Start()
   Thread1.Join()      ' Wait for the thread to finish.
   MsgBox("Thread is done")
End Sub
```

These simple ways of controlling threads, which are useful when you are managing a small number of threads, are difficult to use with large projects. The next section discusses some advanced techniques you can use to synchronize threads.

Advanced Synchronization Techniques

Multithreaded applications often use wait handles and monitor objects to synchronize multiple threads. These sections explain how to use the following .NET Framework classes when synchronizing threads: AutoResetEvent Class, Interlocked Class, ManualResetEvent Class, Monitor Class, Mutex Class, ReaderWriterLock Class, Timer Class, WaitHandle Class

Wait Handles

Wait handles are objects that signal the status of one thread to another thread. Threads can use wait handles to notify other threads that they need exclusive access to a resource. Other threads must then wait to use this resource until the wait handle is no longer in use. Wait handles have two states, *signaled* and *nonsignaled*. A wait handle that is not owned by any thread is in the *signaled* state. A wait handle that is owned by a thread is in the *nonsignaled* state.

Threads request ownership of a wait handle by calling one of the wait methods, such as **WaitOne**, **WaitAny**, or **WaitAll**. The wait methods are blocking calls that are similar to the **Join** method of an individual thread.

- If no other thread owns the wait handle, the call immediately returns **True**, the wait handle's status is changed to nonsignaled, and the thread that owns the wait handle continues to run.
- If a thread calls one of a wait handle's wait methods, but the wait handle is owned by another thread, the calling thread will either wait for a specified time (if a timeout is specified) or wait indefinitely (if no timeout is specified) for the other thread to release the wait handle. If a timeout is specified and the wait handle is released before the timeout expires, the call returns **True**. Otherwise, the call to wait returns **False**, and the calling thread continues to run.

Threads that own a wait handle call the **Set** method when they are done or when they no longer need the wait handle. Other threads can reset the status of a wait handle to nonsignaled by either calling the **Reset** method or by calling **WaitOne**, **WaitAll**, or **WaitAny** and successfully waiting for a thread to call **Set**. **AutoResetEvent** handles are automatically reset to nonsignaled by the system after a single waiting thread has been released. If no threads are waiting, the event object's state remains signaled.

There are three kinds of wait handles commonly used with Visual Basic .NET: mutex objects, **ManualResetEvent**, **AutoResetEvent**. The last two are often referred to as synchronization events.

Mutex Objects

Mutex objects are synchronization objects that can only be owned by a single thread at a time. In fact, the name, mutex, is derived from the fact that ownership of mutex objects is mutually exclusive. Threads request ownership of the mutex object when they require exclusive access to a resource. Because only one thread can own a mutex object at any time, other threads must wait for ownership of a mutex object before using the resource.

The **WaitOne** method causes a calling thread to wait for ownership of a mutex object. If a thread terminates normally while owning a mutex object, the state of the mutex object is set to signaled and the next waiting thread gets ownership.

Synchronization Events

Synchronization events are used to notify other threads that something has occurred or that a resource is available. Do not be fooled by the fact that these items use the word *event*. Synchronization events, which are unlike other Visual Basic events, are really wait handles. Like other wait handles, synchronization events have two states, signaled and nonsignaled. Threads that call one of the wait methods of a synchronization event must wait until another thread signals the event by calling the **Set** method. There are two synchronization event classes. Threads set the status of **ManualResetEvent** instances to signaled using the **Set** method. Threads set the status of **ManualResetEvent** instances to nonsignaled using the **Reset** method or when control returns to a waiting **WaitOne** call. Instances of the **AutoResetEvent** class can also be set to signaled using **Set**, but they automatically return to nonsignaled as soon as a waiting thread is notified that the event became signaled.

Monitor Objects and SyncLock

Monitor objects are used to ensure that a block of code runs without being interrupted by code running on other threads. In other words, code in other threads cannot run until code in the synchronized code block has finished.

Suppose, for example, that you have a program that repeatedly and asynchronously reads data and displays the results. With operating systems that use preemptive multitasking, a running thread can be interrupted by the operating system to allow time for some other thread to run. Without synchronization, it is possible that you could get a partially updated view of the data if the object that represents the data is modified by another thread while the data is being displayed. Monitor objects guarantee that a section of code will run without being interrupted. Visual Basic .NET provides the **SyncLock** and **End SyncLock** statements to simplify access to monitor objects. Visual C#® .NET uses the **Lock** keyword in the same way.

Note Access to an object is locked out only if the accessing code is contained within a **SyncLock** block on the same object instance.

For information on the **SyncLock** statement, see SyncLock Statement

Interlocked Class

You can use the methods of the **Interlocked** class to prevent problems that can occur when multiple threads attempt to simultaneously update or compare the same value. The methods of this class let you safely increment, decrement, exchange, and compare values from any thread. The following example shows how to use the **Increment** method to increment a variable that is shared by procedures running on separate threads.

```
Sub ThreadA(ByRef IntA As Integer)
   System.Threading.Interlocked.Increment(IntA)
End Sub

Sub ThreadB(ByRef IntA As Integer)
   System.Threading.Interlocked.Increment(IntA)
End Sub
```

For information on the Interlocked Class, see Interlocked Class

ReaderWriter Locks

In some cases, you may want to lock a resource only when data is being written and permit multiple clients to simultaneously read data when data is not being updated. The **ReaderWriterLock** class enforces exclusive access to a resource while a thread is modifying the resource, but it allows non-exclusive access when reading the resource. ReaderWriter locks are a useful alternative to exclusive locks that cause other threads to wait, even when those threads do not need to update data.

For information on the ReaderWriterLock Class, see ReaderWriterLock Class

Deadlocks

Thread synchronization is invaluable in multithreaded applications, but there is always the danger of *deadlocks* where multiple threads wait for each other. Analogous to when cars are stopped at a four-way stop and each person is waiting for another to go, deadlocks bring everything to a halt. Needless to say, avoiding deadlocks is important. There are many ways to get into deadlock situations but careful planning is key to avoiding them. You can often predict deadlock situations by diagramming multithreaded applications before you start coding.

Delegates and the AddressOf Operator | Multithreading in Components | WaitOne Method | WaitAll Method | WaitAny Method

Thread Pooling

Thread pooling is a form of multithreading where tasks are added to a queue and automatically started as threads are created. With thread pooling, you call the **Threadpool**.**QueueUserWorkItem** method with a delegate for the procedure you want to run, and Visual Basic .NET creates the thread and runs your procedure. The following example shows how you could use thread pooling to start several tasks.

```
Sub DoWork()
   Dim TPool As System.Threading.ThreadPool
   ' Queue a task
   TPool.QueueUserWorkItem(New System.Threading.WaitCallback _
                        (AddressOf SomeLongTask))
   ' Queue another task
   TPool.QueueUserWorkItem(New System.Threading.WaitCallback _
                        (AddressOf AnotherLongTask))
End Sub
```

Thread pooling is useful when you want to start many separate tasks without individually setting the properties of each thread. Each thread starts with a default stack size and priority. By default, up to 25 thread pool threads can run per system processor. Additional threads in excess of the limit can be queued, but they do not start until other threads finish.

One advantage of thread pooling is that you can pass arguments in a state object to the task procedure. If the procedure you are calling requires more than one argument, you can cast a structure or an instance of a class into an **Object** data type.

Thread Pool Parameters and Return Values

Returning values from a thread pool thread is not straightforward. The standard way of returning values from a function call is not allowed because Sub procedures are the only type of procedure that can be queued to a thread pool. One way you can provide parameters and return values is by wrapping the parameters, return values, and methods in a wrapper class as described in Parameters and Return Values for Multithreaded Procedures. An easer way to provide parameters and return values is by using the optional **ByVal** state object variable of the **QueueUserWorkItem** method. If you use this variable to pass a reference to an instance of a class, the members of the instance can be modified by the thread pool thread and used as return values. At first it may not be obvious that you can modify an object referred to by a variable that is passed by value. This is possible because only the object reference is passed by value. When you make changes to members of the object referred to by the object reference, the changes apply to the actual class instance.

Structures cannot be used to return values inside state objects. Because structures are value types, changes that the asynchronous process makes do not change the members of the original structure. Use structures to provide parameters when return values are not needed.

Thread Timers

The **Threading.Timer** class is useful to periodically run a task on a separate thread. For example, you could use a thread timer to check the status and integrity of a database or to back up critical files. The following example starts a task every two seconds and uses a flag to initiate the **Dispose** method that stops the timer. This example posts status to the output window, so you should make this window visible by pressing Control+Alt+O before you test the code.

```
Class StateObjClass
' Used to hold parameters for calls to TimerTask
      Public SomeValue As Integer
      Public TimerReference As System.Threading.Timer
      Public TimerCanceled As Boolean
End Class

Sub RunTimer()
   Dim StateObj As New StateObjClass()
   StateObj.TimerCanceled = False
   StateObj.SomeValue = 1
   Dim TimerDelegate As New Threading.TimerCallback(AddressOf TimerTask)
   ' Create a timer that calls a procedure every 2 seconds.
   ' Note: There is no Start method; the timer starts running as soon as
   ' the instance is created.
   Dim TimerItem As New System.Threading.Timer(TimerDelegate, StateObj, _
                                               2000, 2000)
   StateObj.TimerReference = TimerItem  ' Save a reference for Dispose.

   While StateObj.SomeValue < 10 ' Run for ten loops.
      System.Threading.Thread.Sleep(1000)  ' Wait one second.
   End While

   StateObj.TimerCanceled = True  ' Request Dispose of the timer object.
End Sub

Sub TimerTask(ByVal StateObj As Object)
   Dim State As StateObjClass = CType(StateObj, StateObjClass)
   Dim x As Integer
   ' Use the interlocked class to increment the counter variable.
   System.Threading.Interlocked.Increment(State.SomeValue)
   Debug.WriteLine("Launched new thread  " & Now)
   If State.TimerCanceled Then    ' Dispose Requested.
      State.TimerReference.Dispose()
      Debug.WriteLine("Done  " & Now)
   End If
End Sub
```

Thread timers are particularly useful when the System.Windows.Forms.Timer Class is unavailable, such as when you are developing console applications.

System.Threading Namespace | SyncLock Statement

Multithreading with Forms and Controls

While multithreading is best suited to running procedures and class methods, you can also use it with forms and controls. If you do so, be aware of the following points:

- Whenever possible, execute the methods of a control only on the thread with which it was created. If you must call a method of a control from another thread, you must use the `Control.Invoke` style of calling the method.
- Do not use the **SyncLock** statement to lock threads that manipulate controls or forms. Because the methods of controls and forms sometimes call back to a calling procedure, you can end up inadvertently creating a deadlock — a situation in which two threads wait for each other to release the lock, causing the application to halt.

Walkthrough: Multithreading

This walkthrough demonstrates how to create a multithreaded application that searches a text file for occurrences of a word. The walkthrough consists of four main parts:

- Defining a class with a method that can be run on a thread independently
- Handling events raised by other threads
- Starting a new thread to run a method
- Implementing a `Cancel` button that stops the thread

To build the code example for this topic

1. Open a new Visual Basic .NET Windows Application project, and create a form named `Form1`.
2. Add two buttons and four text boxes to `Form1`.
3. Name the objects as shown in the following table.

Object	Property	Setting
First button	**Name**, **Text**	Start, Start
Second button	**Name**, **Text**	Cancel, Cancel
First text box	**Name**, **Text**	SourceFile, ""
Second text box	**Name**, **Text**	CompareString, ""
Third text box	**Name**, **Text**	WordsCounted, "0"
Fourth text box	**Name**, **Text**	LinesCounted, "0"

4. Add a label next to each text box. Set the **Text** property for each label as shown in the following table.

Object	Property	Setting
First label	**Text**	Source File
Second label	**Text**	Compare String
Third label	**Text**	Matching Words
Fourth label	**Text**	Lines Counted

To define the method that will run on a separate thread

1. From the **Project** menu, choose **Add Class** to add a class to the project. The **Add New Item** dialog is displayed.
2. Select **Class** from the templates window and type `Words.vb` in the name field.
3. Click **Open**. The `Words` class is displayed.
4. Add an Option Compare statement to the top of the `Words` class module, above the **Class** statement:

```
Option Compare Text ' Case insensitive search.
' Use Option Compare Binary for case sensitive search.
```

5. Add the following code to the `Words` class:

```
Public Class Words
   Private strloc As Integer
   Private RemainingString As String
   Private SourceString As String
   Public SourceFile As String
   Public CompareString As String
   Public WordCount As Integer
   Private LinesCounted As Integer = 0
   Public Event Status(ByVal LinesCounted As Integer, _
                       ByVal WordsMatched As Integer)
   Public Event FinishedCounting(ByVal NumberOfMatches As Integer)

   Sub CountWords()
      Dim f As System.IO.File
```

```
        Dim mystream As System.IO.StreamReader
        Dim mystr As String = " " ' Initialize to not empty.

        If SourceFile = System.String.Empty _
           Or CompareString = System.String.Empty Then
           MsgBox("You must set the SourceFile " & _
                  " and CompareString fields before calling CountWords.")
           Exit Sub
        End If

        If f.Exists(SourceFile) = False Then
           MsgBox("Error; Unable to open the input file.")
           Exit Sub
        End If

        Try
           mystream = f.OpenText(SourceFile) ' Open a new stream.
           ' Do until the stream returns Nothing at end of file.
           Do Until IsNothing(mystr)
              mystr = mystream.ReadLine
              WordCount += CountInString(1, mystr, CompareString)
              LinesCounted += 1 ' Increment line count.
              ' Raise an event so the form can monitor progress.
              RaiseEvent Status(LinesCounted, WordCount)
           Loop
        Catch eof As IO.EndOfStreamException
        ' No action is necessary, the end of the stream has been reached.
        Catch IOExcep As IO.IOException
           ' Some kind of error occurred.
           MsgBox(IOExcep.Message)
        Finally
           mystream.Close() ' Close the file.
        End Try
        RaiseEvent FinishedCounting(WordCount)
     End Sub

     Private Function CountInString(ByVal StartingPoint As Integer, _
                                    ByVal SourceString As String, _
                                    ByVal CompareString As String) As Integer
        ' This function counts the number of times
        ' a word is found in a sentence.
        ' If the word is found, the function is called recursively on
        ' the remainder of the string.
        strloc = Strings.InStr(StartingPoint, SourceString, CompareString)
        If strloc <> 0 Then
           CountInString += 1
           CountInString += CountInString(strloc + Strings.Len(CompareString), _
                                          SourceString, CompareString)
        End If
     End Function
  End Class
```

To handle events from the thread

- Add the following event handlers to your main form:

```
  Sub FinishedCountingEventHandler(ByVal WordCount As Integer)
     ' This event handler is called when the word-counting thread
     ' raises a FinishedCounting event indicating that
```

```
    ' the whole file has been checked. The WordCount parameter
    ' is the number of matches found.
    Me.WordsCounted.Text = CStr(WordCount)
    MsgBox("Finished counting words.")
End Sub
Sub LineCountEventHandler(ByVal LinesCounted As Integer, _
                          ByVal WordsMatched As Integer)
    ' This event handler is called when the word-counting thread
    ' raises a status event after reading each line
    ' from the source file.
    Me.LinesCounted.Text = CStr(LinesCounted)
    Me.WordsCounted.Text = CStr(WordsMatched)
End Sub
```

To start and call a new thread that runs the WordCount method

1. Add the following code to the **Declarations** section of `Form1`:

```
Dim Thread As System.Threading.Thread
```

2. Add the following procedure to your program:

```
Sub StartThread()
    Dim WC As New words()
    Me.WordsCounted.Text = "0"
    ' Set the values of some object fields, because
    ' you cannot create a thread and pass it a method
    ' signature that contains parameters.
    WC.CompareString = Me.CompareString.Text ' The string to look for.
    WC.SourceFile = Me.SourceFile.Text       ' The file to search.
    ' Associate an event handler with the event that
    ' is raised when the new thread is done.
    AddHandler WC.FinishedCounting, AddressOf _
                                    FinishedCountingEventHandler
    ' Associate an event handler with the event that
       ' is raised after each line is read.
    AddHandler WC.Status, AddressOf LineCountEventHandler
    ' Create the new thread.
    Thread = New System.Threading.Thread(AddressOf WC.CountWords)
    ' Start the new thread.
    Thread.Start()
End Sub
```

3. Call the `StartThread` method from the `Start` button on your form:

```
Private Sub Start_Click(ByVal sender As System.Object, _
                        ByVal e As System.EventArgs) Handles Start.Click
    StartThread()
End Sub
```

To implement a Cancel button that stops the thread

1. Add the following procedure to your main form:

```
Protected Sub StopThread(Thread as System.Threading.Thread)
'   Call StopThread from a Cancel button procedure.
    Thread.Abort()
End Sub
```

2. Call the `StopThread` procedure from the `click` event handler for the `Cancel` button.

```
Private Sub Cancel_Click(ByVal sender As System.Object, _
                         ByVal e As System.EventArgs) _
                         Handles Cancel.Click
   StopThread(Thread)
End Sub
```

Testing

You can now test the application to make sure it works correctly.

To test the application

1. Press **F5** to run the application.
2. When the form is displayed, enter the file path in the `sourceFile` textbox for a file you want to test. For example, assuming your test file is named Test.txt, enter C:\Test.txt.
3. In the second text box, enter a word or phrase for the application to search for in the text file.
4. Click the `Start` button. The `LinesCounted` button should begin incrementing immediately. The application displays the message "Finished Counting" when it is done.

To test the Cancel button

1. Press **F5** to start the application, and enter the file name and search word as described in the previous procedure. Make sure that the file you choose is large enough so you will have time to cancel the procedure before it is finished.
2. Click the `Start` button to start the application.
3. Click the `Cancel` button. The application should stop counting immediately.

Error Handling

This application contains some basic error handling. It detects and handles source file problems and blank search strings. You can make this program more robust by handling other errors, such as exceeding the maximum number of words or lines that can be counted.

Processing Drives, Folders, and Files

Visual Basic allows you to process drives, folders, and files in several different ways: through the use of the .NET **System.IO** model, through traditional methods such as the **FileOpen** and **Write** functions, and through the File System Object (FSO) model. The following sections discuss these methods in detail.

In This Section

File Access with Visual Basic .NET
Discusses how to use the .NET **System.IO** model to work with files, drives, and folders.

File Access with Visual Basic Run-Time Functions
Discusses how to process files directly to create, manipulate, and store text and other data.

Accessing Files with FileSystemObject
Covers using **FileSystemObject** to create and manipulate files.

Choosing Among File I/O Options in Visual Basic .NET

Visual Basic .NET presents three possible approaches to file I/O for the programmer: runtime methods contained in Visual Basic .NET; FileSystemObject; and the Common Language Runtime File methods.

File Methods in Visual Basic .NET

The **Microsoft.VisualBasic** namespace is populated by a host of functions and methods familiar to users of earlier versions of Visual Basic. While some names have shifted slightly, the vast majority are the same: **Dir**, **Input**, **Print**, **Seek**, **Write**, and so forth.

A few changes have occurred in the functions used in these different types of file access. The most noticeable change is the substitution of the **FilePut/FilePutObject** and **FileGet/FileGetObject** functions for **Put** and **Get**. In Visual Basic .NET, **FilePut** and **FileGet** map to the **Put** and **Get** functions; **FilePutObject** and **FileGetObject** are used to write an object of type **Object** (the equivalent of **Variant** type in earlier versions of Visual Basic) to the file. For more information, see Variant Type Constant Changes in Visual Basic .NET.

Advantages and Disadvantages

Two principal advantages of the functions provided by the Visual Basic .NET runtime are familiarity and ease of use. The core functionality of Visual Basic .NET, which remains familiar, intuitive, and flexible, provides a comfortable launching place for exploration of .NET.

Similarly, upgrading a program written in an earlier version of Visual Basic to its .NET counterpart or creating an application that interacts well with applications written in earlier versions should prove relatively simple. For more information on upgrading previous versions of code, see Preparing a Visual Basic 6.0 Application for Upgrading.

The Visual Basic .NET functions also provide binary file access, which the **FileSystemObject** object (described in the next section) does not, making it a better choice when working with variable length fields.

Finally, there are no special considerations, such as the need to import namespaces, when using the Visual Basic .NET built-in file I/O functions from within Visual Basic .NET.

The fact that Visual Basic .NET file I/O functions do not support writing types other than **String**, **Date**, **Integer**, **Long**, **Single**, **Double**, **Decimal**, and structures and arrays of those types poses a disadvantage when using these functions. Beyond this, classes cannot be serialized and performance in such cases may not be as optimal as using the **System.IO** classes directly.

Code Examples

The following example checks to see if a file exists and if so, uses the **FileCopy** function to copy it to a new file.

```
Private Sub CopyFiles()
   Dim checkFile As String
   checkFile = Dir$("c:\test.txt")
   If checkFile = "test.txt"
      FileCopy "c:\test.txt", "c:\new.txt"
   End If
End Sub
```

The following example uses the **FilePut** function, which corresponds to the **Put** function in previous versions of Visual Basic, to write data to a file. Three records of the structure `CustomerRecord` are written to the file.

```
Structure CustomerRecord
   Public OrderNumber As Integer
   Public Name As String
   Public OrderDate As Date
End Structure

Sub WriteData()
   Dim MyRecord As CustomerRecord
   Dim RecordNumber As Integer
   Dim RecordDate As Date
   ' Open file for random access.
   FileOpen(1, "C:\TESTFILE.txt", OpenMode.Binary)
   For RecordNumber = 1 To 3   ' Loop 3 times.
      MyRecord.OrderNumber = RecordNumber    ' Define OrderNumber.
```

```
      MyRecord.OrderDate = RecordDate          ' Define OrderDate.
      MyRecord.Name = "My Name" & RecordNumber ' Create a string.
      FilePut(1, MyRecord)                 ' Write record to file.
   Next RecordNumber
   FileClose(1)
End Sub
```

.NET Framework Classes

The **System.IO** namespace contains **File** and **Directory** classes, which provide the basic functionality that manipulates files and directories. Because all the methods are static or shared members of these objects, you can use them directly without creating an instance of the class first.

Advantages and Disadvantages

Venturing into the common language runtime yields a rich class library. For example, the **System.IO** namespace provides services beyond basic file I/O, such as the **FileSystemWatcher** class, which allows you to monitor changes to files, and the **FileInfo** and **DirectoryInfo** classes, which allow you to gather information about a specified file or directory. For more information, see FileSystemWatcher Class, FileInfo Class, and DirectoryInfo Class.

Similarly, the common language runtime offers the **FileIOPermission** class, which allows you to control access to files and directories. This may be particularly important for developers working with Web Forms, which by default run within the context of a special local user named ASPNET, which is created as part of the ASP.NET and .NET Framework installations. When such an application requests access to a resource, that request is made within the context of that user. However, by default, the ASPNET user has limited permissions, which may prevent them from performing actions such as writing to a file from a Web application. For more information, see FileIOPermission Class.

The common language runtime is also compatible with other .NET languages, such as Visual C#™, and may aid in achieving consistency across applications, which may be particularly important at the enterprise level.

Lack of familiarity with the common language runtime may create difficulties for a Visual Basic programmer who is still becoming familiar with these new approaches. If you are in that category, you may prefer to rely on the methods you know well.

Code Examples

The following example uses the **StreamReader** class to read the contents of a text file.

```
Imports System
Imports System.IO
Function ReadTextFile(ByVal path As String) As String
   Dim sr As System.IO.StreamReader
   Dim Contents As String
   sr = New StreamReader(path)
   Contents = sr.ReadToEnd()
   sr.Close()
   Return Contents
End Function
```

The following code reverses the previous example, using the same approach with the **StreamWriter** class to write to a text file.

```
Imports System
Imports System.IO
Sub WriteTextFile(ByVal path As String, ByVal value As String)
Dim sr As StreamWriter
Dim Contents As String
   sr = New StreamWriter(path)
   sr.Write(value)
   sr.Close()
End Sub
```

FileSystemObject

Like the functions and methods provided by the **Microsoft.VisualBasic** namespace, the **FileSystemObject** object will be familiar to users of previous versions of Visual Basic.

The FileSystemObject (FSO) model presents files, directories, and drives as COM objects, each with their own properties and methods. You can create and manipulate these objects and use their properties to discover information such as a directory's contents, a file's size, the time an object was created, and so on. You access the objects representing the system's files, directories, and drives by creating and accessing an instance of the **FileSystemObject** object.

The FSO object model, which is in the Microsoft Scripting Runtime type library (Scrrun.dll), supports the creation and manipulation of text files through the **TextStream** object. For more information, see TextStream Object. The **FileStream** class exposes a stream around a file, allowing both synchronous and asynchronous read and write operations on a file system as well as buffering input and output for better performance. Information is written to the buffer and the contents of the buffer are written to the file only when the buffer is full or a **Close** method is called. For more information, see FileStream Class.

Advantages and Disadvantages

The primary advantage of the FSO is that it gathers a number of file I/O functions into a single object. By creating an instance of the object, you can access its methods and properties.

The FSO object model is also well suited to threading. It provides a constructor for asynchronous I/O, such as when using the **BeginRead** and **BeginWrite** methods, which enables the main thread to continue, allowing the user to process the data later. Multiple I/O requests can be pending at the same time.

However, there are several disadvantages to the FSO. As noted earlier, it works only with text files. To manipulate binary files, you must use pointers to an address in memory, or byte arrays, which are not supported by the object.

Moreover, when you read or write a large amount of content, the information stored in the buffer may create a big memory hit. Finally, you cannot manage permissions or file and folder attributes.

Code Example

The following example uses an instance of the **FileSystemObject** object to read a file and write its contents.

```
Public Class UsesScripting
   Public Shared Sub Main()
      Dim fileSystem As New Scripting.FileSystemObject()
      Dim file As Scripting.TextStream
      file = fileSystem.OpenTextFile("c:\test.txt", _
      Scripting.IOMode.ForReading, False, _
      Scripting.Tristate.TristateUseDefault)
      Dim contents As String = file.ReadAll()
      Console.WriteLine(contents)
      file.Close()
   End Sub
End Class
```

File Access with Visual Basic .NET

The .NET **System.IO** model provides an object-based tool for working with folders and files. Like **FileSystemObject** (as described in Accessing Files with FileSystemObject), it allows you to use standard *object.method* syntax — with its own set of properties, methods, and events — to process text and data, giving your applications the ability to read from and write to files easily.

The .NET **System.IO** namespace includes a class library that facilitates string, character, and file manipulation. These classes contain properties, methods, and events for creating, copying, moving, and deleting files. And, since both strings and numeric data types are supported, they also allow you to incorporate data types in files. The most commonly used classes are **FileStream**, **BinaryReader, BinaryWriter**, **StreamReader**, and **StreamWriter**.

System.IO Namespace
Summarizes synchronous and asynchronous reading and writing between data streams and files.

File Access Through the FileStream Class

The **FileStream** class provides access to files, including the standard input, output, and error devices. You use it with the **File** class, which aids in creating **FileStream** objects and provides routines for creating, copying, deleting, moving, and opening files. Another class, **Path**, provides a means of manipulating strings that represent folder or file paths.

The **FileAccess**, **FileMode**, and **FileShare** enumerations contain the flags used by the constructors of the **FileStream** class, and affect how the underlying file is created, opened, and shared. The **FileEnumerator** enumeration provides a means of reading the information maintained by the host file system for a specified group of files and directories. The **FileEnumerator** enumeration allows read access to information such as access and creation dates.

When used in conjunction with **FileEnumerator**, the **FileAttributes** enumeration enables the gathering of file-specific information. The **FileAttributes** enumeration returns the file's stored attributes, such as whether it is an archive, compressed, a directory, encrypted, hidden, read-only, a system file, or a temporary file.

File Access Through StreamReader and StreamWriter Classes | Drive and Folder Access | System.IO Namespace |
Code: Reading from a Text File (Visual Basic) | Code: Writing Text to a File (Visual Basic)

File Access Through BinaryReader and BinaryWriter Classes

The **BinaryReader** and **BinaryWriter** classes may be more familiar to Visual Basic users as **DataReader** and **DataWriter**. Although the names have been changed for the System.IO Namespace model, the underlying functionality remains the same. The **BinaryReader** class is used for reading strings and elementary data types, whereas the **BinaryWriter** class writes elementary types in binary data from a sequential text file (sometimes referred to as a *text stream*).

> **Security Note** When writing to files, an application may need to create a file if the file to which it is trying to write does not exist. To do so, it needs permission for the directory in which the file is to be created. However, if the file already exists, the application only needs **Write** permission to the file itself. Wherever possible, it is more secure to create the file during deployment and only grant **Write** permission to that file, rather than to the entire directory. It is also more secure to write data to user directories than to the root directory or the Program Files directory.

The following example demonstrates how to read and write to a newly created file:

```
Imports System.IO
Private Sub MyButton_Click (ByVal sender As System.Object, ByVal e As System.EventArgs) Handl
es MyButton.Click)
' Code throws an exception if the file already exists.
   Dim fs As FileStream = New FileStream("c:\data.txt", _
   FileMode.CreateNew)
   Dim w As BinaryWriter = New BinaryWriter(fs)
   Dim r As BinaryReader = New BinaryReader(fs)
   Dim i As Integer

   ' Takes the series of integers and stores them in a buffer.
   For i = 0 To 11
      w.Write(CStr(i))
   Next

   ' Sets the pointer to the beginning of the file.
   w.Seek(0, SeekOrigin.Begin)

   ' Writes the contents of the buffer to the console.
   For i = 0 To 11
      Console.WriteLine(CStr(i))
   Next

   ' Reads from file and writes it one character at a time.
   For i = 0 To 11
      Dim NewString As String
      NewString = r.read()
      Console.WriteLine(NewString)
   Next
End Sub
```

> **Note** Both **BinaryReader** and **BinaryWriter** read and write information as binary rather than text. To process text information, see File Access Through StreamReader and StreamWriter Classes.

File Access with Visual Basic .NET | File Access Through the FileStream Class |
File Access Through StreamReader and StreamWriter Classes | Drive and Folder Access | Serialization | System.IO Namespace |
Code: Reading from a Text File (Visual Basic) | Code: Writing Text to a File (Visual Basic)

File Access Through StreamReader and StreamWriter Classes

The System.IO Namespace class allows you to read and write characters to and from files as streams, or contiguous groups of data, using specific encoding to convert characters to and from bytes. It includes a pair of classes, **StreamReader** and **StreamWriter**, which enable you to read or write a sequential stream of characters to or from a file. The **StreamReader** and **StreamWriter** classes mirror the functionality of the **BinaryReader** and **BinaryWriter** classes, but they read and write information as text rather than binary. For more information, see File Access Through BinaryReader and BinaryWriter Classes.

The **StreamReader** class is derived from an abstract class called **TextReader**, which reads characters from a stream or file. The **StreamWriter** class is derived from an abstract class called **TextWriter**, which writes characters to a stream or file.

> **Security Note** When writing to files, an application may need to create a file if the file to which it is trying to write does not exist. To do so, it needs permission for the directory in which the file is to be created. However, if the file already exists, the application only needs **Write** permission to the file itself. Wherever possible, it is more secure to create the file during deployment and only grant **Write** permission to that file, rather than to the entire directory. It is also more secure to write data to user directories than to the root directory or the Program Files directory.

Reading From and Writing to Files

The following example writes a line of text to a file.

```
' Write text to a file
Sub WriteTextToFile()
    Dim file As New System.IO.StreamWriter("c:\test.txt")
    file.WriteLine("Here is the first line.")
    file.Close()
End Sub
```

The following example reads the text from a file into one string variable and writes the text to the console.

```
Sub ReadTextFromFile()
    Dim file As New System.IO.StreamReader("c:\test.txt")
    Dim words As String = file.ReadToEnd()
    Console.WriteLine(words)
    file.Close()
End Sub
```

The following example adds text to an existing file.

```
Sub AppendTextToFile()
    Dim file As New System.IO.StreamWriter("c:\test.txt", True)
    file.WriteLine("Here is another line.")
    file.Close()
End Sub
```

The following example reads one line at a time from a file and prints each line to the console.

```
Sub ReadTextLinesFromFile()
    Dim file As New System.IO.StreamReader("c:\test.txt")
    Dim oneLine As String
    oneLine = file.ReadLine()
    While (oneLine <> "")
        Console.WriteLine(oneLine)
        oneLine = file.ReadLine()
    End While
    file.Close()
End Sub
```

File Encoding

Both the **StreamReader** and **StreamWriter** classes use UTF-8 encoding by default. UTF-8 encoding handles Unicode characters correctly and ensures that localized versions of the operating system are consistent with each other.

You can detect a file's encoding automatically with **StreamReader**, or you can specify it as a parameter on a constructor.

StreamWriter takes an encoding parameter on its constructor. If encoding is specified, Visual Basic writes to the file to indicate the encoding used.

File Access Through the FileStream Class | Drive and Folder Access | System.IO Namespace |
Code: Reading from a Text File (Visual Basic) | Code: Writing Text to a File (Visual Basic)

Drive and Folder Access

Visual Basic .NET allows you to work with folders and drives via the **Directory** class. This class gives you the ability to create, edit, and delete folders, as well as maintain the drives on your system. Frequently used methods of the **Directory** class are listed in the following table:

Method	Description
CreateDirectory	Creates all directories specified by *path*.
Delete	Overloaded. Deletes a directory and its contents.
Exists	Determines whether the given path refers to an existing **DirectoryInfo** object on dis k.
GetDirectories	Overloaded. Gets an array of directories in the current directory.
GetDirectoryRoot	Returns the root portion of the specified path.
GetLogicalDrives	Retrieves names of logical drives on current machine.
GetParent	Retrieves parent directory of the specified path.
Move	Moves a **DirectoryInfo** object and its contents to a new path.
SetCurrentDirectory	Sets the current directory.

Walkthrough: Manipulating Files Using .NET Framework Methods

After completing this walkthrough, you will be able to open and read a file using the **StreamReader** class, check to see if a file is being accessed, search for a string within a file read with an instance of the **StreamReader** class, and write to a file using the **StreamWriter** class.

Creating the Application

Start Visual Studio and begin the project by creating a form that the user can use to write to the designated file.

To create the project

1. On the **File** menu, point to **New**, and then click **Project**.

   The **New Project** dialog box appears.

2. In the **Project Types** pane, click **Visual Basic Projects**, and then click **Windows Application** in the **Templates** pane.
3. In the **Name** box type MyDiary and click **OK**.

   Visual Studio adds the project to **Solution Explorer**, and the **Windows Forms Designer** opens.

4. Add the controls in the following table to the form and set the corresponding values for their properties.

Object	Properties	Value
Button	Name Text	Submit Submit Entry
Button	Name Text	Clear Clear Entry
TextBox	Name Text Multiline	Entry Please enter something . False

Writing to the File

To add the ability to write to a file via the application, use the **StreamWriter** class. **StreamWriter** is designed for character output in a particular encoding, whereas the **Stream** class is designed for byte input and output. Use **StreamWriter** for writing lines of information to a standard text file. For more information on the **StreamWriter** class, see StreamWriter Class. To add writing functionality:

1. To open the **Code Editor**, select **Code** from the **View** menu.
2. Because the application references the **System.IO** namespace, add the following statements at the very beginning of your code, before the class declaration for the form, which begins `Public Class Form1`.

   ```
   Imports System
   Imports System.IO
   ```

3. Before writing to the file, you must create an instance of a **StreamWriter** class. Return to the **Windows Forms Designer** by selecting **Designer** from the **View** menu.
4. Double-click the **Submit** button to create a click event handler for the button and then add the following code to it:

   ```
   Dim fw As StreamWriter
   ```

   Note The Visual Studio Integrated Development Environment (IDE) returns to the **Code Editor** after the double-click and positions the cursor within the event handler where you should add the code.

5. To write to the file, use the **Write** method of the **StreamWriter** class. Add the following code directly after `Dim fw As`

`StreamWriter`. You do not need to worry that an exception will be thrown if the file is not found, because it will be created if it doesn't already exist.

```
    Dim ReadString As String
    Try
       'Pass the file path and name to the StreamWriter constructor.
       'Indicate that Append is True, so file will not be overwritten.
       fw = New StreamWriter("C:\MyDiary.txt", True)
       ReadString = Entry.Text
       fw.WriteLine(ReadString)
    Finally
       'Close the file.
       fw.Close()
    End Try
```

6. To make sure that the user cannot submit a blank entry, add the following code directly aft`er Dim ReadString As String`.

```
If (Entry.Text = "" Or Entry.Text = "Please enter something.") Then
   Entry.Text = "Please enter something."
   Return
End If
```

7. 8Because this is a diary, the user will want to assign a date to each entry. Insert the following code after `fw = New StreamWriter("C:\MyDiary.txt", True)` to set the variable `Today` to the current date.

```
Dim Today As DateTime
Today = Now.ToString
fw.Write(CStr(today))
fw.Write(ControlChars.CrLf)
```

8. Finally, attach code to clear the TextBox. Add the following code to the Clear button's Click event.

```
Entry.Text = ""
```

To display the diary, additional functionality will display the latest entry in the **DisplayEntry** TextBox. Further refinement adds a ComboBox that displays various entries and from which a user can select an entry to display in the **DisplayEntry** TextBox. An instance of the **StreamReader** class will read from MyDiary.txt. Like the **StreamWriter** class, **StreamReader** is intended for use with text files.

For this section of the walkthrough, add the controls in the following table to the form and set the corresponding values for their properties.

Object	**Properties**	**Value**
TextBox	Name	DisplayEntry
	Visible	False
	Size	120,60
	Multiline	True
Button	Name	Display
	Text	Display
Button	Name	GetEntries
	Text	Get Entries

ComboBox	Name Text Enabled	PickEntries Select an Entry False

To populate the ComboBox

1. The **PickEntries** ComboBox will be used to display the dates on which a user submitted each entry, so the user can select an entry from a specific date. Create a Click event handler to the **GetEntries** button and add the following code to it:

```
Dim fr As StreamReader
Dim FileString As String
FileString = ""
Try
   fr = New StreamReader("C:\MyDiary.txt")
   PickEntries.Items.Clear()
   PickEntries.Enabled = True
   Do
      FileString = fr.ReadLine
      If IsDate(FileString) Then
         PickEntries.Items.Add(FileString)
      End If
   Loop Until (FileString Is Nothing)
Finally
   fr.Close()
End Try
PickEntries.Enabled = True
```

2. To test your code, press **F5** to compile the application and click **Show Entries**. Click the dropdown arrow in the ComboBox to display the entry dates.

To choose and display individual entries

1. Create a Click event handler for the `Display` button and add the following code to it:

```
Dim fr As StreamReader
Dim ReadString As String
'Make sure ReadString begins empty.
ReadString = ""
Dim FileString As String
fr = New StreamReader("C:\MyDiary.txt")
'If no entry has been selected, show the whole file.
If PickEntries.Enabled = False Or PickEntries.SelectedText Is Nothing Then
   Do
      'Read a line from the file into FileString.
      FileString = fr.ReadLine
      'add it to ReadString
      ReadString = ReadString & ControlChars.CrLf & FileString
   Loop Until (FileString = Nothing)
Else
   'An entry has been selected, find the line that matches.
   Do

      FileString = fr.ReadLine
   Loop Until FileString = CStr(PickEntries.SelectedItem)
   FileString = CStr(PickEntries.SelectedItem) & ControlChars.CrLf
   ReadString = FileString & fr.ReadLine
```

```
    'Read from the file until EOF or another Date is found.
    Do Until ((fr.Peek < 0) Or (IsDate(fr.ReadLine)))
        ReadString = ReadString & fr.Readline
    Loop
End If
fr.Close()
DisplayEntry.Visible = True
DisplayEntry.Text = ReadString
```

2. To test your code, press **F5** to compile the application, submit an entry. Click **Show Entries**, select an entry from the ComboBox, and then click **Display**. The contents of the selected entry appears in the `DisplayEntry` TextBox.

Finally, additional functionality enables users to delete or modify an entry by using Delete Entry and Edit Entry buttons. Both buttons remain disabled unless an entry is being displayed.

1. Add the controls in the following table to the form and set the corresponding values for their properties.

Object	Properties	Value
Button	Name	DeleteEntry
	Text	Delete Entry
	Enabled	False
Button	Name	EditEntry
	Text	Edit Entry
	Enabled	False
Button	Name	SubmitEdit
	Text	Submit Edit
	Enabled	False

2. Add the following code to the `Display` button's click event, after `DisplayEntry.Text = ReadString`.

```
DeleteEntry.enabled = True
```

3. Create a Click event handler for the `DeleteEntry` button and add the following code:

```
Dim fr As StreamReader
Dim ReadString As String
Dim WriteString As String
Dim ConfirmDelete As MsgBoxResult
fr = New StreamReader("C:\MyDiary.txt")
ReadString = fr.ReadLine
' Read through the textfile
Do Until (fr.Peek < 0)
      ReadString = ReadString & vbCrLf & fr.ReadLine
Loop
WriteString = Replace(ReadString, DisplayEntry.Text, "")
fr.Close()
' Check to make sure the user wishes to delete the entry
ConfirmDelete = MsgBox("Do you really wish to delete this entry?", _ MsgBoxStyle.OKCancel
)
If ConfirmDelete = MsgBoxResult.OK Then
    File.Delete("C:\MyDiary.txt")
    Dim fw As StreamWriter = File.CreateText("C:\MyDiary.txt")
    fw.WriteLine(WriteString)
    fw.Close()
    ' Reset controls on the form
```

```
    DisplayEntry.Text = ""
    PickEntries.Text = ""
    PickEntries.Items.Clear()
    PickEntries.Enabled = False
    DeleteEntry.Enabled = False
End If
```

4. When a user displays an entry, the `EditEntry` button becomes enabled. Add the following code to the click event of the `Display` button after `DisplayEntry.Text = ReadString`:

```
EditEntry.Enabled = True
```

5. Create a Click event handler for the `EditEntry` button and add the following code to it:

```
Entry.Text = DisplayEntry.Text
SubmitEdit.Enabled = True
```

6. Create a Click event handler for the `SubmitEdit` button and add the following code to it:

```
Dim fr As StreamReader
Dim ReadString As String
Dim WriteString As String
If Entry.Text = "" Then
    MsgBox("Use Delete to Delete an Entry")
    Return
End If
fr = New StreamReader("C:\MyDiary.txt")
ReadString = fr.ReadLine
Do Until (fr.Peek < 0)
    ReadString = ReadString & vbCrLf & fr.ReadLine
Loop
WriteString = Replace(ReadString, DisplayEntry.Text, Entry.Text)
fr.Close()
File.Delete("C:\MyDiary.txt")
Dim fw As StreamWriter = File.CreateText("C:\MyDiary.txt")
fw.WriteLine(WriteString)
fw.Close()
DisplayEntry.Text = Entry.Text
Entry.Text = ""
EditEntry.Enabled = False
SubmitEdit.Enabled = False
```

To test your code, press **F5** to compile the application. Click **Show Entries**, select an entry, and then click **Display**. The entry displays in the `DisplayEntry` TextBox. Click **Edit Entry**. The entry displays in the `Entry` TextBox. Edit the entry in the `Entry` TextBox and click **Submit Edit**. Open the MyDiary.txt file to confirm your correction. Now select an entry and click **Delete Entry**. When the MsgBox requests confirmation, click **OK**. Close the application and open MyDiary.txt to confirm the deletion.

File Access with Visual Basic Run-Time Functions

In earlier versions of Visual Basic, files were processed using the Open statement and other related statements and functions. Visual Basic .NET includes compatible functions as part of its library, specifically in the **System.IO.File** namespace (for details, see System.IO Namespace). The topics in this section show how to process files directly to create, manipulate, and store text and other data using available file I/O functions.

In This Section

File Access Types and Functions
Explains statements and functions used with the three types of file access.
Sequential File Access
Covers how to open files for sequential access and edit their data.
Random File Access
Provides an overview of creating and reading random-access files.
Binary File Access
Discusses creating and accessing binary files.
Data Access Functions
Describes statements typically used to write data to and read data from files.
Walkthrough: Manipulating Files and Folders in Visual Basic .NET
Demonstrates how to read and write to a text file using Visual Basic Run-Time functions.

System.IO Namespace
Summarizes synchronous and asynchronous reading and writing between data streams and files.

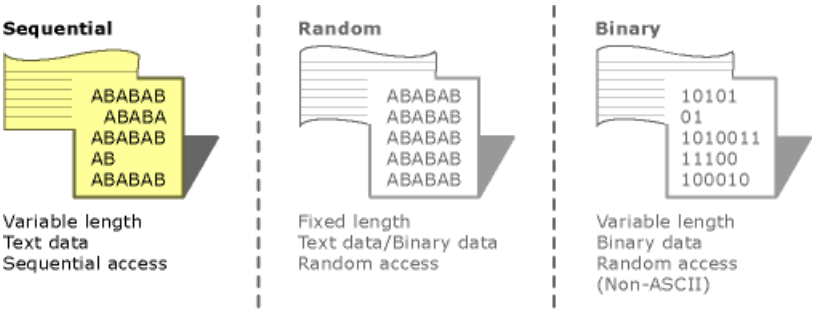
File Access Types and Functions

By itself, a file is nothing more than a series of related bytes of data on a disk. When your application accesses a file, it must assume whether the bytes represent characters, data records, integers, strings, and so on. You tell your application what to assume by specifying the file's access type.

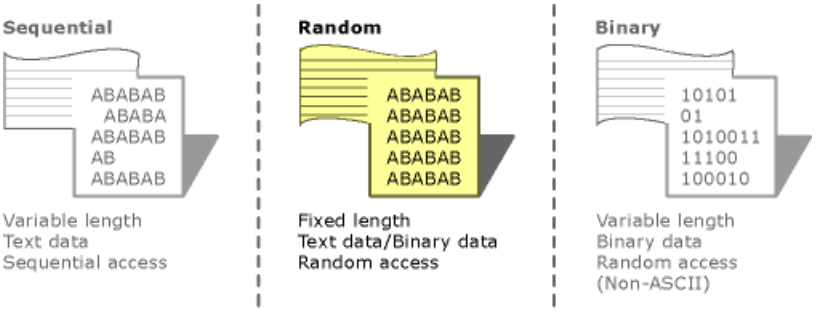
The file access type you use depends on what kind of data the file contains. Visual Basic provides three types of file access:

- Sequential, for reading and writing text files in continuous blocks.
- Random, for reading and writing text or binary files structured as fixed-length records.
- Binary, for reading and writing arbitrarily structured files.

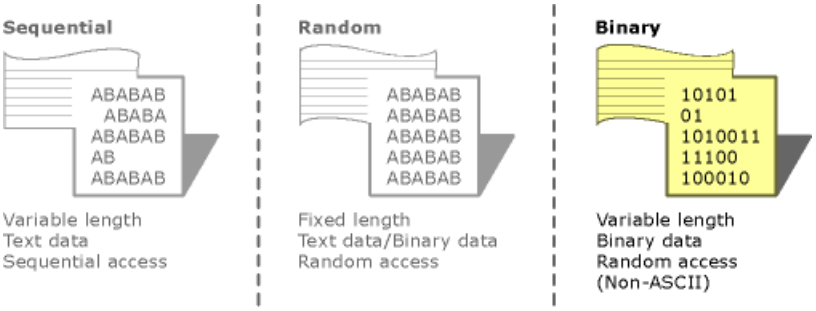
Sequential access is designed for use with plain text files. Each character in the file is assumed to represent either a text character or a text-formatting sequence, such as a newline character. Data is stored as ANSI characters.



A file opened for *random access* is assumed to be composed of a set of identical-length records, or sets of fields containing information. You can employ user-defined types to create records made up of numerous fields, each of which can have different data types. Data is stored as binary information.



Binary access allows you to use files to store data in any form that suits your needs, whether it is numeric, string, or both. Binary access is similar to random access except that no assumptions are made about data type or record length. However, you must know precisely how the data was written to the file to retrieve it correctly. For example, if you store a series of names and phone numbers, you need to remember that the first field (the name) is text and the second field (the phone number) is numeric.



File Access Functions

The following functions are used with sequential, random, and binary file access.

Dir Function	EOF Function	FileCopy Function
FileDateTime Function	FileLen Function	FreeFile Function
GetAttr Function	Loc Function	LOF Function
Seek Function	SetAttr Function	

The following table lists all file access functions available for each of the three types of direct file access.

Functions	Sequential	Random	Binary
FileClose Function	X	X	X
FileOpen Function	X	X	X
Input Function	X		X
InputString Function	X		
LineInput Function	X		
Print, PrintLine Functions	X		
Write, WriteLine Functions	X		

Note For additional information on file access functions, look up the function topic in the index.

Data Access Functions | Sequential File Access | Random File Access | Binary File Access

Sequential File Access

Using **System.IO** is the recommended way to create text files, but should you need to use older text file-creation methods, this section shows you how.

Sequential access works best when you want to process files consisting only of text, such as files created with a typical text editor, not files in which data is divided into a series of records. Sequential access is not well suited for storing long series of numbers, because each number is stored as a character string. Thus, a four-digit number would require four bytes of storage instead of the two bytes required to store the same number as an integer.

In This Section

Opening Files for Sequential Access
Describes how to gain access for input, output, and appending characters within a file.

Editing Files Opened for Sequential Access
Explains using **Line Input**, **InputString**, and **Input** to edit files.

Writing Strings to Sequential-Access Files
Discusses how to use **Print** and **Write** functions to store strings in text files.

Related Sections

Accessing Files with FileSystemObject
Discusses creating objects, accessing their properties, and using the appropriate methods.

Opening Files for Sequential Access

When you open a file for sequential access, you must specify whether to input characters from the file (**Input** mode), output characters to the file (**Output** mode), or append characters to the file (**Append** mode).

To open a file for sequential access

- Use the FileOpen Function with the following syntax:

```
FileOpen(FileNumber, FileName, OpenMode.Input)
```

When you open a sequential file for **Input**, the file must already exist; otherwise an error occurs. When you try to open a nonexistent file for **Output** or **Append**, however, the **FileOpen** statement creates the file first and then opens it.

After opening a file for an **Input**, **Output**, or **Append** operation, you must close it with the FileClose Function statement before reopening it for another type of operation.

> **Security Note** When writing to files, an application may need to create a file if the file to which it is trying to write does not exist. To do so, it needs permission for the directory in which the file is to be created. However, if the file already exists, the application only needs **Write** permission to the file itself. Wherever possible, it is more secure to create the file during deployment and only grant **Write** permission to that file, rather than to the entire directory. It is also more secure to write data to user directories than to the root directory or the Program Files directory.

Sequential File Access | Editing Files Opened for Sequential Access | File Access with Visual Basic Run-Time Functions | FileOpen Function | Random File Access | Binary File Access | Writing Strings to Sequential-Access Files

Editing Files Opened for Sequential Access

To edit a file, you must first read its contents to program variables, then change the variables, and finally, write the variables back to the file. The following sections discuss how to edit records opened for sequential access.

To read strings from files

1. Retrieve the contents of a text file by opening it for **Input**.
2. Use the LineInput, InputString, or Input functions to copy the file into program variables.

Visual Basic provides statements and functions that read and write sequential files one character at a time or one line at a time. For example, the following code fragment reads a file line by line:

```
Dim LinesFromFile, NextLine As String, FileNum As Integer
Do Until EOF(FileNum)
   Nextline = LineInput(FileNum)
   LinesFromFile = LinesFromFile & NextLine & Chr(13) & Chr(10)
Loop
```

Although the **LineInput** function recognizes the end of a line when it comes to the carriage return/line feed sequence, it does not include that sequence when it reads the line into the variable. If you want to retain the carriage return/line feed, your code must add it.

You can use the **InputString** function to copy a specified number of characters from a file to a variable, provided the variable is large enough. For example, the following code uses **InputString** to copy `CharCount` number of characters to a variable:

```
LinesFromFile = InputString(FileNum, CharCount)
```

You can also use the **Input** function, which reads a list of numbers and/or string expressions from a file. For example, to read in a line from a mailing list file, you might use the following statements:

```
Input(FileNum, fname)
Input(FileNum, lname)
Input(FileNum, street)
Input(FileNum, city)
Input(FileNum, state)
Input(FileNum, zip)
```

See Also

Sequential File Access | Opening Files for Sequential Access | File Access with Visual Basic Run-Time Functions | FileOpen Function | Random File Access | Binary File Access | Writing Strings to Sequential-Access Files

Writing Strings to Sequential-Access Files

You can add data in the form of strings to existing files via the Print Function or in the form of numbers and string expressions through the Write Function.

To write strings to files

1. Use the FileOpen Function to open a text file for **Output** or **Append**.
2. Use the **Print** function to write the strings to the file as in the following example, which a text editor might use to copy the contents of a text box into a file:

```
Print(FileNum, TheBox.Text)
```

Visual Basic also supports the **Write** function, which writes a list of numbers and/or string expressions to a file. It automatically separates each expression with a comma and puts quotation marks around **String** expressions, as illustrated in the following code:

```
Dim AnyString As String, AnyNumber, FileNum As Integer
AnyString = "AnyCharacters"
AnyNumber = 23445
Write(FileNum, AnyString, AnyNumber)
```

The previous code segment writes two expressions to the file specified by `FileNum`. The first contains a string, and the second contains the number 23445. Therefore, Visual Basic writes the following characters (including all punctuation) to the file:

```
"AnyCharacters",23445
```

> **Note** If you are maintaining a database using **Write** and **Input** with sequential access, consider using **FilePutObject** and **FileGetObject** with random or binary access instead; both types of access are better suited to record-oriented data.

One of the primary differences between **Print** and **Write** is that **Print** formats the string, while **Write** does not. For this reason, **Print** does not include quotation marks around the string, which is formatted as the user would like to see it, while **Write** does.

Use a function that writes each string to a new line, such as **PrintLine** or **WriteLine** if you need strings separated by line.

Random File Access

The bytes in random-access files form records of uniform length, each containing one or more fields. A record with one field corresponds to any standard type, such as an integer or fixed-length string. A record with more than one field corresponds to a user-defined type.

In this section you declare, open, edit, and write to a random-access file, using a hypothetical Employee Records database as an example. Each file-access aspect of the example is discussed separately in the topics listed immediately below.

In This Section

Declaring Variables for Random File Access
Discusses creating variables and user-defined types for random access.
Opening Files for Random Access
Explains how to use the **FileOpen** statement to work on existing files.
Editing Files Opened for Random Access
Explains how to move records from a random file into variables.
Writing Variables to Records
Covers how to write variables back to records after editing their values.

Related Sections

File Access with Visual Basic Run-Time Functions
Covers processing files directly to create, manipulate, and store text and other data.
Accessing Files with FileSystemObject
Discusses creating objects, accessing their properties, and using the appropriate methods.

Declaring Variables for Random File Access

Before your application opens a file for random access, it should declare all variables required to handle data from the file. This includes user-defined types, which correspond to records in the file, as well as standard types for other variables that hold data related to processing a random-access file.

Before opening a file for random access, define a structure that corresponds to the records the file contains or will contain. For example, a hypothetical Employee Records database might contain a user-defined data type called `Person` as follows:

```
Structure Person
   Public ID As Integer
   Public MonthlySalary As Decimal
   Public LastReviewDate As Long
   <VBFixedString(15)> Public FirstName As String
   <VBFixedString(15)> Public LastName As String
   <VBFixedString(15)> Public Title As String
   <VBFixedString(150)> Public ReviewComments As String
End Structure
```

Declaring Field Variables in a Structure Definition

Because all records in a random-access file must have the same length, it is often useful for string elements in a user-defined type to have a fixed length also. In the `Person` type declaration above, for example, `FirstName` and `LastName` have a fixed length of 15 characters. To declare a fixed-length string, set its length with the **VBFixedString** attribute.

If the actual string contains fewer characters than the fixed length of the string element to which it is written, Visual Basic fills the trailing spaces in the record with blanks (character code 32). If the string is longer than the field size, Visual Basic truncates it. (If you use variable-length strings, the total size of any record stored with the FilePut Function or retrieved with the FileGet Function must not exceed the record length specified in the FileOpen Function).

After defining a structure that corresponds to a typical record, declare any other variables that your application needs to process a file opened for random access. The Employee Records database, for instance, declares `Employee`, `Position`, and `LastRecord` variables, as follows:

```
' Declare a record variable.
Public Employee As Person
' Track the current record.
Public Position As Long
' Get the number of the last record in the file.
Public LastRecord As Long
```

Opening Files for Random Access | Editing Files Opened for Random Access | Writing Variables to Records |
File Access with Visual Basic Run-Time Functions | Sequential File Access | Binary File Access

Opening Files for Random Access

After you create the file, you need to open it to make any modifications.

To open a file for random access

- Use the FileOpen Function with the following syntax:

```
FileOpen(FileNumber, FileName, OpenMode.Random, , , RecordLength)
```

FileNumber and *FileName* specify the file number and name of the file to be opened, respectively. *RecordLength* specifies the size of each record in bytes. If *RecordLength* is less than the actual length of the record written to the file, an error is generated. If *RecordLength* is greater than the actual length of the record, the record is written, although some disk space may be wasted. Note that every **String** variable in Visual Basic stores an ASCII string, and that you must specify the byte length of that ASCII string.

> **Security Note** When writing to files, an application may need to create a file if the file to which it is trying to write does not exist. To do so, it needs permission for the directory in which the file is to be created. However, if the file already exists, the application only needs **Write** permission to the file itself. Wherever possible, it is more secure to create the file during deployment and only grant **Write** permission to that file, rather than to the entire directory. It is also more secure to write data to user directories than to the root directory or the Program Files directory.

In Declaring Variables for Random File Access, a hypothetical Employee Records database first defined a `Person` data type and then declared a record variable of that type as well as two other variables for processing records. The following code continues the Employee Records example, demonstrating how to open a random-access file to accept `Employee` data of user-defined type `Person`:

```
Sub Main()
   Dim FileNum As Integer, RecLength As Long, Employee As Person
   ' Calculate the record length.
   RecLength = Len(Employee)
   ' Get the next available file number.
   FileNum = FreeFile
   ' Open the new file with the FileOpen statement.
   FileOpen(FileNum, "MYFILE.DAT", OpenMode.Random, , , RecLength)
End Sub
```

Declaring Variables for Random File Access | Editing Files Opened for Random Access | Writing Variables to Records | File Access with Visual Basic Run-Time Functions | Sequential File Access | Binary File Access

Editing Files Opened for Random Access

To edit a random-access file, first read records from the file into program variables, and then change the values in the variables. In Declaring Variables for Random File Access and Opening Files for Random Access, a hypothetical Employee Records database defined variables for reading and writing employee records. The following step describes how to read and copy employee records using those variables.

To read and copy records into variables

- Use the FileGetObject Function, which copies a record from the Employee Records file into the `Employee` variable:

  ```
  FileGet(FileNum, Employee, Position)
  ```

  In this line of code, `FileNum` contains the number that the FileOpen Function used to open the file, `Position` contains the number of the record to copy, and `Employee`, declared as the user-defined type `Person`, receives the contents of the record.

Writing Variables to Records

After editing records read into program variables from a random-access file, use the FilePut Function to replace or add records. In Declaring Variables for Random File Access and Opening Files for Random Access, a hypothetical Employee Records database defined variables for reading and writing employee records. The following steps describe how to replace and add employee records using those variables.

To replace a record

- Use **FilePut** to specify the position of the record you want to replace. The Random File Access example illustrates this in the following code:

  ```
  FilePut(FileNum, Employee, Position)
  ```

  This code replaces the record number specified by `Position` with the data in the `Employee` variable.

To add a record

- Using **FilePut**, set the value of the `Position` variable equal to one more than the number of records in the file. To add a record to a file that contains five records, for example, set `Position` equal to 6.

  In the case of the Employee Records example, substituting the following statements for the **FilePut** statement above adds a record to the end of the file instead of overwriting the one specified by `Position`:

  ```
  LastRecord = LastRecord + 1
  FilePut(FileNum, Employee, LastRecord)
  ```

Deleting Records

You can delete a record's contents by clearing its fields, but the record will still exist in the file. In most cases, you don't want empty records in your file because they waste space. To avoid this, you can copy the remaining records to a new file, and then delete the old one; or, you can make a note of the location of the empty record and use that slot on the next insert operation.

To delete a record

- Clear the record's fields.

To remove a deleted record

1. Create a new file.
2. Copy all the valid records from the original file into the new file.
3. Close the original file and use the **Kill** function to delete it.
4. Use the **Rename** function to rename the new file with the name of the original file.

Binary File Access

Use binary access when it is important to keep file size small. Because binary access doesn't require fixed-length fields, the type declaration can omit the string length parameters. This enables you to conserve disk space by building variable-length records.

In This Section

Opening and Closing Files for Binary Access
Describes how to use the **FileOpen** and **FileClose** functions to access a file.

Reading from and Writing to a File Opened for Binary Access
Describes how to read from and write to a file using the **FilePut**, **FilePutObject**, **FileGet** and **FileGetObject** functions.

Related Sections

File Access with Visual Basic Run-Time Functions
Covers processing files directly to create, manipulate, and store text and other data.

Accessing Files with FileSystemObject
Covers using **FileSystemObject** to create and manipulate files.

Opening and Closing Files for Binary Access

Use binary access when it is important to keep file size small. Because binary access doesn't require fixed-length fields, you can conserve disk space by building variable-length records.

To open a file for binary access

- Use the FileOpen Function with the following syntax:

```
FileOpen(FileNumber, FileName, OpenMode.Binary)
```

To close a file for binary access

- Use the FileClose Function with the following syntax:

```
FileClose(FileNumber)
```

As you can see, opening files for binary access differs from Opening Files for Random Access in that the *RecordLength* expression is not specified. (If you do include a record length in a binary-access **FileOpen** function, it is ignored.)

To appreciate binary access, consider the Employee Records example discussed in the Random File Access section. This random-access file uses fixed-length records and fields to store information about employees. As a result, every record in the Employee Records database takes the same number of bytes, regardless of the actual contents of the fields.

You can minimize the size of Employee Records by using binary access. Because you are not required to use fixed-length fields, you can omit the string-length parameters from the type declaration, as in the following code:

```
Structure Person
   ID As Integer
   MonthlySalary As Decimal
   LastReviewDate As Long
   FirstName As String
   LastName As String
   Title As String
   ReviewComments As String
End Structure

Public Employee As Person   ' Defines a record.
```

Each employee record in the Employee Records file now occupies only the exact number of bytes required, because the fields are of variable lengths.

The drawback to binary input/output with variable-length fields is that you cannot randomly access records; you must instead access them sequentially to learn the length of each one. You can still go directly to a specified byte position in a file, but if the fields are of variable length, there is no direct way to know which record is at which byte position.

> **Security Note** When writing to files, an application may need to create a file if the file to which it is trying to write does not exist. To do so, it needs permission for the directory in which the file is to be created. However, if the file already exists, the application only needs **Write** permission to the file itself. Wherever possible, it is more secure to create the file during deployment and only grant **Write** permission to that file, rather than to the entire directory. It is also more secure to write data to user directories than to the root directory or the Program Files directory.

File Access with Visual Basic Run-Time Functions | Sequential File Access | Random File Access | FileOpen Function |FileGet Function |FilePut Function

Reading from and Writing to a File Opened for Binary Access

Binary access provides a number of advantages for certain tasks. For example, you can store information in a specific format, such as .zip, .mpeg or .xls. Binary access is similar to random access except that no assumptions are made about data type or record length. Because binary access does not require fixed-length fields, you can write variable-length fields to such a file. Binary access can thus keep file size smaller than random access because each field can occupy only the space it requires.

To open a file for binary access, specify **OpenMode.Binary** with the **FileOpen** statement. After it has been opened, you can use the same functions to write to the file, such as **FilePut** and **FilePutObject**, that you would with a file opened for sequential or random access. To read from the file, use **FileGet** and **FileGetObject** functions. For more information, see File Access Types and Functions.

> **Security Note** When reading from files, do not make decisions about the contents of a file based on the file name extension. For example, a file named Form1.vb may not be a Visual Basic .NET source file.

The following example uses the **FilePut** function to write a string to a file opened for binary access. It assumes that there is a file named test.txt in the current directory.

```
Private Sub Button1_Click(ByVal sender As System.Object, ByVal e As_
System.EventArgs) Handles Button1.Click
   Dim MyString As String
   Dim ReadString As String
   Dim iFr As Short
   iFr = FreeFile()
   ReadString = CurDir() & "\test.txt"
   FileOpen(iFr, 1, OpenMode.Binary)
   MyString = "new information"
   FilePut(MyString)
   FileClose(iFr)
End Sub
```

The following example uses the **FileGet** function to display the first 15 characters contained in test.txt. Again, this example presupposes that test.txt exists.

```
Private Sub Button1_Click(ByVal sender As System.Object, ByVal e As_
System.EventArgs) Handles Button1.Click
     Dim MyString As String
     Dim ReadString As String
     Dim iFr As Short
     iFr = FreeFile()
     ReadString = CurDir() & "\test.txt"
     FileOpen(iFr, ReadString, OpenMode.Binary)
     MyString = New String(" "c, 15)
     FileGet(iFr, MyString)
     FileClose(iFr)
     MsgBox(MyString)
End Sub
```

You may wish to use information gathered from a file in your code. For example, the following code sample writes the contents of a textfile, test.txt, to a listbox, myListBox. It assumes that the file, test.txt, exists and contains several items separated by carriage returns.

```
Dim myListbox As ListBox
Private Sub Button1_Click(ByVal sender As System.Object, ByVal e As _
System.EventArgs) Handles Button1.Click
   Dim ReadString As String
   Dim iFr As Short
   Dim sTmp As String
   ReadString = CurDir() & "\test.txt"
   iFr = FreeFile()
   FileOpen(iFr, ReadString, OpenMode.Binary)
   sTmp = Space(FileLen(ReadString))
   FileGet(iFr, sTmp)
```

```
        FileClose(iFr)

        Dim strRecords() As String : strRecords = Split(sTmp, vbCrLf)
        'Clear the listbox
        MyListbox.Items.Clear()
        Dim lngRecord As Long
        For lngRecord = LBound(strRecords) To UBound(strRecords)
           myListbox.Items.Add(strRecords(lngRecord))
        Next lngRecord
    End Sub
```

Opening and Closing Files for Binary Access | Binary File Access | Random File Access | Sequential File Access | File Access with Visual Basic Run-Time Functions | FilePut Function | FilePutObject Function | FileGet Function | FileGetObject Function | File Access Types and Functions

Data Access Functions

Working with large amounts of data often requires that data be written to or read from a file. Before either operation can take place, however, the file must first be opened. The FileOpen Function lets you create and access files with one of three types of file access:

- Sequential access (**Input**, **Output**, and **Append** modes) is used for writing text files, such as error logs and reports.
- Random access (**Random** mode) is used to read and write data to a file without closing it. Random-access files keep data in records, which makes it easy to locate information quickly.
- Binary access (**Binary** mode) is used to read or write to any byte position in a file, such as storing or displaying a bitmap image.

  Do not use the **FileOpen** function to manipulate files that are usually edited by a specific application, such as Microsoft Office documents or registry files. Doing so will cause file corruption and loss of file integrity.

The following table shows the statements typically used when writing data to and reading it from files.

Access type	Writing data	Reading data
Sequential	Print, PrintLine Functions Write, WriteLine Functions	InputString Function LineInput Function
Random	FilePut Function	FileGet Function
Binary	FilePut Function	FileGet Function

File Access Types and Functions | Sequential File Access | Random File Access | Binary File Access

Walkthrough: Manipulating Files and Folders in Visual Basic .NET

This walkthrough provides an introduction to the fundamentals of file I/O in Microsoft Visual Basic .NET. To illustrate the features, it creates a small application, FileExplorer, which examines text files within a directory and provides information such as attributes, last access time, and the first 80 characters of the file. It also includes an option that writes the information to a log file.

Creating the Application

To begin the project, create a form from which users can select a directory, choose a file from the directory, and choose the information they want to retrieve about that file.

To create the project

1. On the **File** menu, point to **New**, and then click **Project**.

   The **New Project** dialog box appears.

2. In the **Project Types** pane, click **Visual Basic Projects**, and then click **Windows Application** in the **Templates** pane.
3. In the **Name** box, type FileExplorer to set the project name.

   Visual Studio adds the project to Solution Explorer, and the Windows Forms Designer opens.

4. Add the controls in the following table to the form, and set the corresponding values for their properties.

Object	Properties	Value
TextBox	Name Text	txtDirectory Directory
Button	Name Text	btnSubmit Submit
Button	Name Text	btnExamine Examine
ComboBox	Name Text	LstFilePick Select A File
CheckBox	Name Text Checked	chkAttributes Attributes True
CheckBox	Name Text Checked	chkFileLength File Length True
CheckBox	Name Text Checked	chkLastAccess Last Access Time True
CheckBox	Name Text Checked	chkFirstLine Show First Line True

CheckBox	Name	chkSave
	Text	Save Results
	Checked	False

Displaying the Current Directory

The FileExplorer application needs a starting point. Accordingly, the `txtDirectory` TextBox uses the **CurDir** function to return and display a string representing the current path.

To return the current directory

1. Create an event handler for `Form1_Load` by double-clicking the form.

   The Code Editor opens.

2. Add the following code, so the `txtDirectory` TextBox displays the current location.

```
txtDirectory.Text = CurDir()
```

3. Run the program to verify that the **CurDir** function returns the correct path.

   The `txtDirectory` TextBox displays the current directory.

Changing Directories

Since a user may want to select files in a different directory, the application uses the **ChDir** function to switch directories. To change to a different directory, a user enters a new path in the `txtDirectory` TextBox.

To change directories

1. Create a click event handler for `btnSubmit` by double-clicking the control on the form.

   The Code Editor opens.

2. Add the following code to the click event handler.

```
Dim NewPath As String
' NewPath holds the path the user has entered.
NewPath = txtDirectory.Text
' Change the location to NewPath.
ChDir(NewPath)
```

Verifying That a Valid Path Has Been Entered

The **ChDir** function requires the Path parameter, which may or may not include the drive letter. If the path does not specify the drive, **ChDir** uses the current drive. To avoid this potential source of confusion, the application incorporates a **Try...Catch** statement that catches such exceptions as well as exceptions that arise from the submission of a blank path.

To ensure valid paths

1. In the `btnSubmit_Click` event, after the code line `Dim NewPath As String`, add `Dim ErrorMessage As String` on a new line.
2. Before the code line `ChDir(NewPath)`, add a **Try** statement on its own line as follows. If you hit return, the Code Editor will automatically insert `Catch ex As Exception` and `End Try` statements. Remove these; you will add your own in the next step.

```
        Try
```

3. After the code line `ChDir(NewPath)`, add the following:

```
        ' This checks to make sure the path is not blank.
        Catch ex As Exception When NewPath = ""
            ErrorMessage = "You must enter a path."
```

```
        ' This catches errors caused by a path that is not valid.
        Catch
            ErrorMessage = "You must enter a valid path.  If trying" & _
            "to access a different drive, remember to include the drive" & _
            "letter."
        Finally
            ' Display the error message only if one exists.
            If ErrorMessage <> "" Then
               MsgBox(ErrorMessage)
            End If
         End Try
```

Displaying the Contents of the Directory in a ComboBox

To enable the application to display the contents of the current directory, you can use the **Dir** function, which returns a string representing the name of a file, directory, or folder matching a specified pattern. Since the **Dir** function returns only the first matching item, the application includes a **Do Until...Loop** to check each item. The following code added to the Submit button also restricts the types of files listed to .txt files.

> **Note** This process takes advantage of the fact that calling the **Dir** function without arguments leaves the previous matching pattern in place.

To display directory contents

1. Insert `Dim ContentItem As String` at the beginning of the `btnSubmit_Click` event.
2. After the line `End Try` insert:

```
LstFilePick.Items.Clear()
' Only look at the .txt files.
ContentItem = Dir("*.txt")
If ContentItem = "" Then
   ErrorMessage = "No text files found."
   MsgBox(ErrorMessage)
End If
' Iterate through the directory contents.
Do Until ContentItem = ""
   ' Add it to the list.
   lstFilePick.Items.Add(ContentItem)
   ' Move to the next textfile.
   ContentItem = Dir()
Loop
```

The gathered information displays in the `lstFilePick` ComboBox from which you can pick a specific file to examine.

Test the application by running it first on a directory that contains no .txt files and then on one that contains more than one .txt file. In the first instance, the application displays the appropriate error **MsgBox**. In the second, the application creates a list in the ComboBox of all .txt files within the directory specified in the `txtDirectory` TextBox.

Enabling a User to Select a File to Examine

Although the `lstFilePick` ComboBox displays all files in a directory, a user probably wants to select and examine a specific file.

- Create a click event handler for `btnExamine_Click` and add the following code to confirm a file's selection.

```
Dim thisFile As Object
thisFile = lstFilePick.SelectedItem
```

Enabling a user to determine what information to gather

Now that files display in the `lstFilePick` ComboBox, additional code enables a user to specify the reported information. For example, one user might want to merely know the date when the file was last accessed. Another user might want to know a file's size, too. A user checks or unchecks a series of CheckBoxes (`chkAttributes`, `chkLastAccess`, `chkFileLength`, `chkFirstLine`) to customize the results.

To display specific information

1. Declare these variables at the beginning of the `btnExamine_Click` event after **`thisFile = lstFilePick.SelectedItems`**:

```
Dim Attributes As FileAttribute
Dim AttributeResult As String
Dim StringAttributes As String
Dim LastAccess As Date
Dim Length As Long
Dim FirstLine As String
Dim FinalString As String
Dim ErrorMessage As String
Dim NewName As String
NewName = Ctype(thisfile, String)
If thisFile = Nothing Then
    MsgBox("You must select a file to examine.")
    Exit Sub
End If
```

   The **GetAttr** function returns a member of the **FileAttribute** enumeration representing the attributes of a file, directory, or folder. The returned value is a sum of its enumeration values. To determine which attributes are set, use the **And** operator to perform a bitwise comparison between the value returned by **GetAttr** and the value of the file attribute you want.

   > **Note** Because the application inspects only text files, it is reasonable to ignore some values possibly returned by **GetAttr**, such as **Directory**, **Hidden**, and **System**. It should be noted that this example code will be incorrect for files with such attributes.

2. Add the following code to the `btnExamine_Click` event after `NewName = CType(thisFile, String)` to enable a user to check the file's attributes.

```
' Check Attributes.
Dim MultiAttribute as FileAttribute
MultiAttribute = vbReadOnly Or vbArchive
If chkAttributes.Checked = True Then
    Attributes = GetAttr(thisFile)
    If (Attributes And MultiAttribute) = MultiAttribute Then
        AttributeResult = "ReadOnly and Archive"
    ElseIf (Attributes and vbReadOnly) = vbReadOnly Then
        AttributeResult = "ReadOnly"
    ElseIf (Attributes and vbArchive) = vbArchive Then
        AttributeResult = "Archive"
    Else
        AttributeResult = "Normal"
    End If
End If
```

3. Add the following code to the end of the `btnExamine_Click` event.

```
' Check last access time.
If chkLastAccess.Checked = True Then
     LastAccess = FileDateTime(NewName)
End If
```

   The **FileDateTime** function determines the last time the file was accessed. The returned **Date** value indicates the date and time when the file was created or last modified.

4. Add the following code to end of the `btnExamine_Click` event.

```
' Check Length.
If chkFileLength.Checked = True Then
     Length = FileLen(NewName)
End If
```

The **FileLen** function, which determines the length of the file, returns a long value specifying the length of the file in bytes.

5. Add the following code to the end of the `btnExamine_Click` event to enable a user to get the first line of the file.

```
' Check the first line.
If chkFirstLine.Checked = True Then
     Try
          FileOpen(1, NewName, OpenMode.Input)
          FirstLine = (InputString(1, 80))
     Catch ex As Exception
          ErrorMessage = "Something is wrong with the file you " & _
          "are trying to examine. Make sure it is a text " & _
          " file that is not empty or less than 80 characters."
          MsgBox (ErrorMessage)
          Exit Sub
     Finally
          FileClose(1)
     End Try

End If
```

Displaying the Results

To complete the application's functionality, a **MsgBox** reports the gathered information.

To display the results

1. At the beginning of the `btnExamine_Click` event, declare and initialize the following variables after `Dim stringAttributes As String`:

```
stringAttributes = "The attributes of the file are: "
Dim stringLastAccess As String
stringLastAccess = "The file was last accessed on: "
Dim stringLength As String
stringLength = "The file's length, in bytes, is: "
Dim strFirstLine As String
strFirstLine = "The first 80 characters are: "
```

2. At the end of the `If` statement that determines whether or not the `chkAttributes` CheckBox has been checked, add the following before the final `End If`.

```
' Add this to the results messagebox.
FinalString = stringAttributes & AttributeResult & "." & vbCrLf
```

3. At the end of the `If` statement that determines whether or not the `chkLastAccess` CheckBox has been checked, add the following before the final `End If`.

```
' Add to the messagebox.
FinalString = FinalString & stringLastAccess & LastAccess & "." _
& vbCrLf
```

4. At the end of the `If` statement that determines whether or not the `chkFileLength` CheckBox has been checked, add the

following before the final `End If`.

```
' Add to the messagebox.
FinalString = FinalString & stringLength & CStr(Length) & "." _
& vbCrLf
```

5. At the end of the `If` statement that determines whether or not the `chkFirstLine` CheckBox has been checked, add the following before the final `End If`.

```
' Add to the messagebox.
FinalString = FinalString & strFirstLine & Firstline & vbCrLf
```

6. At the very end of the function, add the following before the final `End Sub`.

```
If FinalString = "" Then
     MsgBox("No file attribute checkboxes selected.")
Else
     MsgBox(FinalString)
End If
```

Saving the Results

A user may want to save the results of an examination of a file. Accordingly, add code that checks to see if a log file exists, creates one if necessary, and then writes the results to the log file.

To create a log file

- Add the following to the end of the `btnExamine_Click` event.

```
' Check to see if results should be saved.
If chkSave.Checked = True and finalstring <> "" Then
     ' FileOpen will create the file if it doesn't exist.
     FileOpen(1, "log.txt", OpenMode.Append)
     Writeline (1, finalString)
     FileClose(1)
End If
```

To Test Your Application

1. In the directory of your choice, create a text file named test.txt with the following first line: "This is the first line of the first file. The FileExplorer application examines only text files." In the same directory, create a second text file named test2.txt with the following first line: "This is the first line of the second file. The FileExplorer application examines only text files." The FileExplorer requires a text file whose length is at least 80 characters.
2. Start the application.
3. Type an invalid path and click **Submit**.

   The following message appears: "You must enter a valid path. If trying to access a different drive, remember to include the drive letter."

4. Type the path to the directory that stores test.txt and click **Submit**.

   The `lstFilePick` ComboBox displays the text files.

5. Select test.txt in the `lstFilePick` ComboBox. Make sure all of the checkboxes are selected, and click **Examine**.

   The results form includes the file attributes, the last access date, the length, and the first 80 characters of the file.

6. Select test2.txt in the `lstFilePick` ComboBox, deselect all checkboxes and click **Examine**.

   The following error message appears: "No file attribute checkboxes selected."

7. Select **Attributes** and **Save Results** and click **Examine**.

The results form displays only the file's attributes.

8. Close **FileExplorer**.

   Since you checked the **Save Results** option, FileExplorer generated a log file named log.txt in the same directory as the text files.

To check the log

- In the current directory, open log.txt and confirm that FileExplorer recorded the correct information.

Accessing Files with FileSystemObject

The File System Object (FSO) model provides an object-based tool for working with folders and files. It allows you to use the familiar *object.method* syntax with a rich set of properties, methods, and events to process folders and files. You can also employ the traditional Visual Basic statements and commands.

The FSO model gives your application the ability to create, alter, move, and delete folders, or to determine if and where particular folders exist. It also enables you to get information about folders, such as their names and the date they were created or last modified.

The FSO model makes processing files much easier as well. When processing files, your primary goal is to store data in an efficient, easy-to-access format. You need to be able to create files, insert and change the data, and output (read) the data. Although you can store data in a database, doing so adds a significant amount of overhead to your application. You may not want to have such overhead, or your data access requirements may not call for the extra functionality associated with a full-featured database. In this case, storing your data in a text file or binary file is the most efficient solution.

The FSO model, contained in the Scripting type library (Scrrun.dll), supports the creation and manipulation of text files through the **TextStream** object; however, the FSO model does not support binary files. To manipulate binary files, use the FileOpen Function with the **Binary** keyword.

The following objects make up the FSO model:

Object	Description
FileSystemObject	Allows you to create, delete, gain information about, and generally manipulate drives, folders, and files. Many of the methods associated with this object duplicate those in the other objects.
Drive	Allows you to gather information about a drive attached to the system, such as how much room is available and what its share name is. Note that a "drive" under the FSO model isn't necessarily a h ard disk: it can be a CD-ROM drive, a RAM disk, and so forth. A drive also isn't required to be phys ically attached to the system; it can also be logically connected through a local area network (LAN) .
Folder	Allows you to create, delete, or move folders, as well as query the system about their names, paths , and other information.
File	Allows you to create, delete, or move files, as well as query the system about their names, paths, a nd other information.
TextStream	Enables you to read and write text files.

For information about the various properties, methods, and events in the FSO model, use the Object Browser in Visual Basic by pressing CTRL+ALT+J and looking at the Scripting type library. If the Scripting type library does not appear in the list, create a reference to it as shown in the next section.

Programming in the FSO Model

Programming in the FSO model entails three main tasks:

- Creating a **FileSystemObject** object by using the **CreateObject** method, or by dimensioning a variable as a **FileSystemObject** object.
- Using the appropriate method on the newly created object.
- Accessing the object's properties.

The FSO model is contained in the Scripting type library, which is located in the file Scrrun.dll. If you don't already have a reference to it, you can create one.

To create a reference to the Scripting type library (Scrrun.dll)

1. On the **Project** menu, click **Add Reference**, and then click the **COM** tab.
2. Choose **Microsoft Scripting Runtime** from the **Component Name** list, and then click **Select**.

   You can now use the Object Browser to view the FSO model's objects, collections, properties, methods, events, and constants.

To create a FileSystemObject object

- Dimension a variable as type **FileSystemObject**, as in the following code:

```
Dim fso As New FileSystemObject
```

- or -

- Use the **CreateObject** method to create a **FileSystemObject** object, as in the following code:

```
fso = CreateObject("Scripting.FileSystemObject")
```

In the second example, `Scripting` is the name of the type library, and **FileSystemObject** is the name of the object of which you want to create an instance.

> **Note** The first method works only in Visual Basic, while the second method works either in Visual Basic or VBScript.

> **Security Note** Do not make decisions about the contents of a file based on the file name extension. For example, a file named Form1.vb may not be a Visual Basic .NET source file.

FSO Methods

The following table shows FSO methods and the tasks that they perform:

Task	Command
Create a new object	**CreateFolder** or **CreateTextFile**
Delete a file or folder	**DeleteFile** or **File.Delete**; **DeleteFolder** or **Folder.Delete**
Copy an object	**CopyFile** or **File.Copy**; **CopyFolder** or **Folder.Copy**
Move an object	**MoveFile** or **File.Move**; **MoveFolder** or **Folder.Move**
Access an existing drive, folder, or file	**GetDrive**, **GetFolder**, or **GetFile**

> **Note** The FSO model does not support the creation or deletion of drives.

As you can see, some functionality in the **FileSystemObject** object model is redundant. For example, you can copy a file using either the **CopyFile** method of the **FileSystemObject** object, or you can use the **Copy** method of the **File** object. The methods work the same way; both versions are included to give you maximum programming flexibility.

Note, however, that you don't need to use the **Get** methods for a newly created object, since the **Create** functions already return a handle to it. For example, if you create a new folder using the **CreateFolder** method, you don't need to use the **GetFolder** method to access its properties, such as **Name**, **Path**, or **Size**. Just set a variable to the **CreateFolder** function to gain a handle to the newly created folder, and then access its properties, methods, and events.

Drive Information

The **Drive** object allows you to get information about the various drives attached to a system, either physically or over a network. Its properties contain the following information:

Property	Description
TotalSize	Total size of the drive, in bytes
AvailableSpace, **FreeSpace**	How much space is available on the drive, in bytes
DriveLetter	Letter assigned to the drive
DriveType	Type of drive (removable, fixed, network, CD-ROM, or RAM disk)
SerialNumber	Drive's serial number
FileSystem	Type of file system the drive uses (FAT, FAT32, or NTFS)
IsReady	Whether a drive is available for use
ShareName, **VolumeName**	Name of the share and/or volume
Path, **RootFolder**	Path or root folder of the drive

App.Path, ChDir, ChDrive, and CurDir

If you use the **Path** property (**App.Path**), the **ChDrive** and **ChDir** statements, or the **CurDir** function, be aware that they may return a Universal Naming Convention (UNC) path (that is, one beginning with *Server**Share*...) rather than a drive path (such as e:*Folder*), depending on how you run your program or project.

App.Path returns a UNC path when:

- You run a project after loading it from a network share, even if the network share is mapped to a drive letter.
- You run a compiled executable file from a network share (but only if it is run using a UNC path).

ChDrive cannot handle UNC paths, and it raises an error when **App.Path** returns one. You can handle this error by adding `On Error Resume Next` before the **ChDrive** statement, or by testing the first two characters of **App.Path** to see if they are backslashes.

The command prompt always has a drive path for the current directory, so **CurDir** is set to a drive path. **ChDir** does not raise an error, but it fails to change the directory from a drive path to a UNC path. The only workaround for this situation is to locate a local drive that is mapped to the share specified in the UNC path, or to use network commands to create such a mapping.

If the project is loaded into the Visual Basic development environment from a network share — either a UNC path or a mapped drive path — **App.Path** returns a UNC path when the project is run and **ChDrive** fails and raises an error. **ChDir** does not raise an error, but it fails to change the directory. The only workaround for this situation is to manually set the drive and directory.

If more than one person can open the project on the network share, you can use an MS-DOS environment variable to give each person a customized mapping for the share.

Folder Information

The following table shows the methods for carrying out common folder tasks:

Method	Task
FileSystemObject.CreateFolder	Create a folder.
Folder.Delete or **FileSystemObject.DeleteFolder**	Delete a folder.
Folder.Move or **FileSystemObject.MoveFolder**	Move a folder.
Folder.Copy or **FileSystemObject.CopyFolder**	Copy a folder.
Folder.Name	Retrieve the name of a folder.
FileSystemObject.FolderExists	Find out if a folder exists on a drive.
FileSystemObject.GetFolder	Get an instance of an existing **Folder** object.
FileSystemObject.GetParentFolderName	Find out the name of a folder's parent folder.
FileSystemObject.GetSpecialFolder	Find out the path of a system folder.

Sequential Text Files and FSO

Sequential text files (sometimes referred to as a *text stream*) are useful when you want to read the contents of a file within a **FileSystemObject** object. You can access sequential text files with these methods:

Method	Task
CreateTextFile, **OpenTextFile**, or **OpenAsTextStream**	Create a sequential text file.
Write or **WriteLine**	Add data to a text file.
Read, **ReadLine**, **or ReadAll**	Read data from a text file.
File.Move or **MoveFile**	Move a file.
File.Copy or **CopyFile**	Copy a file.
File.Delete or **DeleteFile**	Delete a file.

Exception Handling

Visual Basic supports structured exception (error) handling, which allows the program to detect and possibly recover from errors during execution. Visual Basic uses an enhanced version of the **Try...Catch...Finally** syntax already supported by other languages such as C++. Structured exception handling combines a modern control structure (similar to **Select Case** or **While**) with exceptions, protected blocks of code, and filters.

Structured exception handling, which is the recommended method of error handling in Visual Basic, makes it easy to create and maintain programs with robust, comprehensive error handlers. Unstructured exception handling using **On Error** can degrade application performance and result in code that is difficult to debug and maintain.

Introduction to Exception Handling

Visual Basic supports both *structured* and *unstructured* exception (error) handling. By placing specific code in your application, you can handle most of the errors users may encounter and enable the application to continue running. Structured and unstructured error handling allow you to plan for potential errors, preventing them from interfering with the intended purpose of the application.

Consider using exception handling in any method that uses operators that may generate an exception, or that calls into or accesses other procedures that may generate an exception.

If an exception occurs in a method that is not equipped to handle it, the exception is propagated back to the calling method , or the previous method. If the previous method also has no exception handler, the exception is propagated back to that method 's caller, and so on. The search for a handler continues up the call stack, which is the series of procedures called within the application. If it fails to find a handler for the exception, an error message is displayed and the application is terminated.

> **Note** A single method can contain either structured or unstructured exception handling, but not both.

Structured Exception Handling

In structured exception handling, blocks of code are encapsulated, with each block having one or more associated handlers. Each handler specifies some form of filter condition on the type of exception it handles. When an exception is raised by code in a protected block, the set of corresponding handlers is searched in order, and the first one with a matching filter condition is executed. A single method can have multiple structured exception handling blocks, and the blocks can also be nested within each other.

The **Try...Catch...Finally** statement is used specifically for structured exception handling. For more information, see Structured Exception Handling.

Unstructured Exception Handling

The **On Error** statement is used specifically for unstructured exception handling. In unstructured exception handling, **On Error** is placed at the beginning of a block of code. It then has "scope" over that block; it handles any errors occurring within the block. If the program encounters another **On Error** statement, that statement becomes valid and the first statement becomes invalid.

Choosing When to Use Structured and Unstructured Exception Handling

Structured exception handling is simply that — using a control structure containing exceptions, isolated blocks of code, and filters to create an exception handling mechanism. This allows your code to differentiate between different types of errors and react in accordance with circumstances. In unstructured exception handling, an **On Error** statement at the beginning of the code handles all exceptions.

Structured exception handling is significantly more versatile, robust, and flexible than unstructured. If possible, use structured exception handling. However, you might use unstructured exception handling under these circumstances:

- You are upgrading an application written in an earlier version of Visual Basic.
- You are developing a preliminary or draft version of an application and you don't mind if the program fails to shut down gracefully.
- You know in advance exactly what will cause the exception.
- A deadline is pressing and you need to take shortcuts.
- Code is trivial or so short that you only need to test the branch of code generating the exception.
- You need to use the **Resume Next** statement, which is not supported in structured exception handling.

You cannot combine structured and unstructured exception handling in the same function. If you use an **On Error** statement, you cannot use a **Try...Catch** statement in the same function.

Regardless of which you choose to handle exceptions within your code, you must take a step back and examine what assumptions that code makes. For example, when your application asks the user to input a telephone number, the following assumptions come into play:

- The user will input a number rather than characters.
- The number will have a certain format.
- The user will not input a null string.
- The user has a single telephone number.

User input might violate any or all of these assumptions. Robust code requires adequate exception handling, which allows your application to recover gracefully from such a violation.

Unless you can guarantee that a method will never throw an exception under any circumstances, allow for informative exception handling. Exception handling should be meaningful. Beyond stating that something went wrong, messages resulting from exception handling should indicate why and where it went wrong. An uninformative message along the lines of "An error has occurred" only frustrates the user.

Types of Errors | Structured Exception Handling | Unstructured Exception Handling

Types of Errors

In Visual Basic, errors (also called *exceptions*) fall into one of three categories: syntax errors, run-time errors, and logic errors.

Syntax Errors

Syntax errors are those that appear while you write your code. Visual Basic checks your code as you type and alerts you if you make a mistake, such as misspelling a word or using a language element improperly. Syntax errors are the most common type of errors. You can fix them easily in the coding environment as soon as they occur.

> **Note** The **Option Explicit** statement is one means of avoiding syntax errors. It forces the programmer to declare, in advance, all the variables to be used in the application. Therefore, when those variables are used in the code, any typographic errors are caught immediately and can be fixed.

Run-Time Errors

Run-time errors are those that appear only after you compile and run your code. These involve code that may appear to be correct in that it has no syntax errors, but that will not execute. For example, you might correctly write a line of code to open a file. But if the file is corrupted, the application cannot carry out the **Open** function, and it stops running. You can fix most run-time errors by rewriting the faulty code, and then recompiling and rerunning it.

Logic Errors

Logic errors are those that appear once the application is in use. They most often take the form of unwanted or unexpected results in response to user actions. For example, a mistyped key or other outside influence might cause your application to stop working within expected parameters, or altogether. Logic errors are generally the hardest type to fix, since it is not always clear where they originate.

Structured Exception Handling

Visual Basic supports structured exception handling, which helps you create and maintain programs with robust, comprehensive error handlers. Structured exception handling is code designed to detect and respond to errors during execution by combining a control structure (similar to **Select Case** or **While**) with exceptions, protected blocks of code, and filters.

Using the **Try...Catch...Finally** statement, you can protect blocks of code that have the potential to raise errors. You can nest exception handlers, and the variables declared in each block will have local scope.

The Try...Catch...Finally Statement

The following code shows the structure of a **Try...Catch...Finally** statement:

```
Try
   ' Starts a structured exception handler.
   ' Place executable statements that may generate
   ' an exception in this block.
Catch [optional filters]
   ' This code runs if the statements listed in
   ' the Try block fail and the filter on the Catch statement is true.
[Additional Catch blocks]
Finally
   ' This code always runs immediately before
   ' the Try statement exits.
End Try
   ' Ends a structured exception handler.
```

The **Try** block of a **Try...Catch...Finally** exception handler contains the section of code you want your error handler to monitor. If an error occurs during execution of any of the code in this section, Visual Basic examines each **Catch** statement within the **Try...Catch...Finally** until it finds one whose condition matches that error. If one is found, control transfers to the first line of code in the **Catch** block. If no matching **Catch** statement is found, the search proceeds to the **Catch** statements of the outer **Try...Catch...Finally** block that contains the block in which the exception occurred. This process continues through the entire stack until a matching **Catch** block is found in the current procedure. If none is found, an error is produced.

The code in the **Finally** section always executes last, just before the error-handling block loses scope, regardless of whether the code in the **Catch** blocks has executed. Place cleanup code, such as that for closing files and releasing objects, in the **Finally** section.

Error Filtering in the Catch Block

Catch blocks allow three options for specific error filtering. In one, errors are filtered based on the class of the exception (in this case `ClassLoadException`), as shown in the following code:

```
Try
   ' "Try" block.
Catch e as ClassLoadException
   ' "Catch" block.
Finally
   ' "Finally" block.
End Try
```

If a `ClassLoadException` error occurs, the code within the specified **Catch** block is executed.

In the second error-filtering option, the **Catch** section can filter on any conditional expression. One common use of this form of **Catch** filter is to test for specific error numbers, as shown in the following code:

```
Try
   ' "Try" block.
Catch When ErrNum = 5 'Type mismatch.
   ' "Catch" block.
Finally
   ' "Finally" block.
End Try
```

When Visual Basic finds the matching error handler, it executes the code within that handler, and then passes control to the **Finally** block.

> **Note** When trying to find a **Catch** block to handle an exception, each block's handler is evaluated until a match is found. Since these handlers can be calls to functions, unexpected side effects may result; for example, such a call might change a public variable that is then used in the code of a different **Catch** block that ends up handling the exception.

As a third alternative, you can combine options one and two and use both for exception handling. Your **Catch** statements should move from most specific to least specific. A **Catch** block by itself will catch all exceptions derived from **System.Exception**, and therefore should always be placed as the last block before **Finally**.

Structured Exception Handler Example

The following example shows another simple error handler based on the **Try...Catch...Finally** statement:

```
Function GetStringsFromFile(ByVal FileName As String) As Collection
   Dim Strings As New Collection
   Dim Stream As System.IO.StreamReader = System.IO.File.OpenText(FileName)   'Open the file.

   Try
      While True   ' Loop terminates with an EndOfStreamException
                   ' error when end of stream is reached.
         Strings.Add(Stream.ReadLine())
       End While
   Catch eos As System.IO.EndOfStreamException
      ' No action is necessary; end of stream has been reached.
   Catch IOExcep As System.IO.IOException
      ' Some kind of error occurred. Report error and clear collection.
      MsgBox(IOExcep.Message)
      Strings = Nothing
   Finally
      Stream.Close()   ' Close the file.
   End Try

   Return Strings
End Function
```

The **Finally** block is always run, regardless of any actions occurring in preceding **Catch** blocks. You cannot use **Resume** or **Resume Next** in structured exception handling.

> **Note** Any exception other than the **IOException** class or the **EndOfStreamException** class is propagated back to the caller unhandled.

The Exception Class

To facilitate the use of structured exception handling, Visual Basic provides the ability to separate standard code from exception handling code. Exception handling code accesses an instance of the **Exception** class, which allows you to retrieve information about any exception you encounter.

Whenever an exception is thrown, the global **Err** object is set, and a new instance of an **Exception** class is created.

The properties of the **Exception** class aid in identifying the code location, type, and cause of exceptions. For example, the **StackTrace** property lists the called methods that led up to the exception, helping you find where the error occurs in the code. The **Message** property returns a text message describing the error; you can alter it to make a cryptic message easier to understand. If you do not supply an error message text string, the default is used. **HelpLink** gets or sets a link to an associated help file. **Source** gets or sets a string containing the name of the object causing the error or the name of the assembly where the exception originated.

> **Note** Avoid writing code that tests for specific error messages, since messages can change between versions of the class that originally produced them. Instead, test for the Exception type or use the exception number from the global **Err** object.

Introduction to Exception Handling | Types of Errors | Structured Exception Handling | Unstructured Exception Handling | The Err Object | Exception Class | Source Property

Creating Your Own Exceptions

There are two defined subclasses of exceptions in the Exception base class: System.Exception and Application.Exception.

System.Exception is the class from which the .NET Framework derives the pre-defined common language runtime exception classes. It is thrown by the common language runtime when nonfatal errors occur. System.Exception does not provide information about the cause of the exception.

You can create your own application exception classes by inheriting them from the Application.Exception class. Follow good coding practices by ending the class name of your exception with the word "Exception" — for example, OutOfMoneyException or TooMuchRainException.

The following example defines an exception class and defines three constructors for it, each of which takes different parameters.

```
Imports System
Public Class GardenException
   Inherits System.ApplicationException
   Public Sub New()
   End Sub
   ' Creates a Sub New for the exception that allows you to set the
   ' message property when thrown.
   Public Sub New(Message As String)
      MyBase.New(Message)
   End Sub
   ' Creates a Sub New that can be used when you also want to include
   ' the inner exception.
   Public Sub New(Message As String, Inner As Exception)
      MyBase.New(Message)
   End Sub
End Class
```

Note When using remoting in combination with user-defined exceptions, you must ensure that the metadata for your user-defined exceptions is available to code executing remotely, including exceptions that occur across application domains.

Walkthrough: Structured Exception Handling

While you can still employ the **On Error** statement to handle exceptions in your code, Visual Basic .NET also supports structured exception handling, which enables you to create and maintain programs with comprehensive error handling. In structured exception handling, blocks of code test for specific circumstances and react accordingly.

This walkthrough uses the creation of a simple application to demonstrate how to add structured exception handling to a program. It explains how to use the **Try...Catch...Finally** statement to handle exceptions, and how to perform error filtering within **Catch** blocks.

> **Note** You cannot combine both structured and unstructured exception handling within a single procedure.

Creating the Application

The application in this walkthrough is a customer order form for a company that sells teddy bears. The user interface consists of the following controls: a **TextBox** for the customer's name, two **ComboBox** controls to select the color and size of the bear, and an **Order** button. When the user enters the requested information and clicks the **Order** button, the application displays a summary of the order.

To create the application

1. From the **File** menu, select **New**, and then select **Project**. The **New Project** dialog box appears.
2. In the **Project Types** window, select **Visual Basic Projects** if it is not already selected, and then choose **Windows Application** from the **Templates** window.
3. In the **Name** box, set the project name to `TeddyBearProject`. The project is added to Solution Explorer, and the Windows Forms Designer opens.
4. Add the controls in the following table to the form, and set their properties as specified.

Control	Properties	Property Values
Label	Name Text	customerLabel Bear Order Form
TextBox	Name Text	customerName Customer Name
Label	Name Text	bearColorLabel Available Colors
ComboBox	Name Items Text	BearColor Black, Brown, Spotted Bear Color
Label	Name Text	bearSizeLabel Available Sizes
ComboBox	Name Items Text	BearSize Small, Normal, Large Bear Size
Button	Name Text	Order Order

Adding Functionality

Now that the controls and their properties are added and set, you must place code behind them to make the application functional. The following code handles the **Click** event for the **Order** button and displays a message to the customer.

To add functionality to the form and its controls

- Add the following code to the **Order** button's **Click** event:

```
Private Sub order_Click(ByVal sender As System.Object, _
   ByVal e As System.EventArgs) Handles Order.Click
   Dim bearOrder As String
   bearOrder = _
     String.Format("You have ordered a {0} {1} bear.", _
     bearSize.SelectedItem, bearColor.SelectedItem)
   MessageBox.Show(bearOrder)
```

```
End Sub
```

The application is now ready for you to add structured exception handling code.

Adding a Try...Catch Block

To ensure that the customer has specified a color for the bear, add a **Try...Catch** statement. Keep the following considerations in mind:

- A **Catch** clause with no identifier catches all exceptions.
- A **Catch** clause with a **When** clause catches exceptions only when the expression evaluates to **True**; the type of the expression must be implicitly convertible to **Boolean**.

To add a simple Try...Catch block

- Add the following code to the **Order** button's **Click** event after the section that tests the size and color values, that is, after `String.Format(("You have ordered a {0} {1} bear.", BearSize.SelectedItem, BearColor.SelectedItem)`. This code throws an exception if it encounters an invalid color value.

```
Try
   If ((BearColor.SelectedIndex < 0) or _
         (BearColor.SelectedIndex > 2)) Then
      Throw New System.Exception()
   End If
' The Catch statement handles errors caused by a lack of bear color.
Catch ex As Exception When BearColor.SelectedIndex < 0
   bearOrder = String.Format("You must select a bear color!")
Finally
   Beep () ' Beep at the end.
End Try
```

To add an additional Catch clause

1. Add a new item, "Purple", to the `BearColor` **ComboBox** control.
2. 8Add the following code after the code line `bearOrder = String.Format("You must select a bear color!")`:

```
Catch ex As Exception When BearColor.SelectedIndex = 3
   bearOrder = String.Format("There are no bears of that color.")
```

You can add as many **Catch** clauses as necessary to your code.

Testing

You can now test the application to make sure it works correctly.

To build and run the application

1. From the **Build** menu, select **Build TeddyBearProject**.
2. Press F5 to run the application. The main form appears.

To test the application

1. Enter a name in the **Customer name** text box, and then select a color and size for the bear from the **Available Colors** and **Available Sizes** combo boxes.
2. Click the **Order** button. If you specified either **Black**, **Brown**, or **Spotted** as the color in the previous step, a message appears stating the size and color of the bear you ordered.

   If you do not specify a color, a message appears prompting you to do so.

3. Click **OK** to cancel the message.
4. In the **Available Colors** text box, select **Purple**, and then click the **Order** button. A message appears stating that purple bears are not available.

On Error Statement | Try...Catch...Finally Statements | Structured Exception Handling | Throw Statement | Throwing Exceptions from Components

Unstructured Exception Handling

In *unstructured exception handling*, you place an **On Error** statement at the beginning of a block of code, and it handles any errors occurring within that block. When an exception is raised in a procedure after the **On Error** statement executes, the program branches to the line argument specified in the **On Error** statement. The line argument, which is a line number or line label, indicates the exception handler location.

Sometimes a call is made from the original procedure to another procedure, and an exception occurs in the called procedure. In such cases, if the called procedure does not handle the exception, the exception propagates back to the calling procedure, and execution branches to the line argument.

> **Note** Unstructured error handling using **On Error** can degrade application performance and result in code that is difficult to debug and maintain. Structured error handling is the recommended method.

On Error GoTo Line

The **On Error GoTo Line** statement assumes that error-handling code starts at the line specified in the required *line* argument. If a run-time error occurs, control branches to the line label or line number specified in the argument, activating the error handler. The specified line must be in the same procedure as the **On Error GoTo Line** statement; otherwise, Visual Basic generates a compiler error. The following example illustrates the use of an error handler with a line label:

```
Sub TestSub
   On Error GoTo ErrorHandler
      ' Code that may or may not contain errors.
   Exit Sub

   ErrorHandler:
      ' Code that handles errors.
      Resume
End Sub
```

The example contains an error handler named `ErrorHandler`. If any code in the `TestSub` subroutine generates an error, Visual Basic immediately executes the code that follows the `ErrorHandler` label. At the end of the error-handling block, the **Resume** statement passes control back to the line of code where the error first occurred. The rest of the subroutine then continues executing as if the error did not occur.

> **Note** You must place an **Exit Sub** statement immediately before the error-handling block. Otherwise, Visual Basic runs the error-handling code when it reaches the end of the subroutine, causing unwanted or unexpected results.

On Error Resume Next

The **On Error Resume Next** statement specifies that in the event of a run-time error, control passes to the statement immediately following the one in which the error occurred. At that point, execution continues. **On Error Resume Next** enables you to put error-handling routines where errors will occur, rather than transferring control to another location in the procedure.

> **Note** If your procedure calls another procedure, the **On Error Resume Next** statement becomes inactive during the execution of the called procedure. Therefore, you should place an **On Error Resume Next** statement in each called procedure that needs one. This is necessary because the **Resume Next** behavior applies only to the procedure containing the **On Error Resume Next** statement. If an unhandled error occurs in a called procedure, the exception propagates back to the calling procedure, and execution resumes on the statement following the call. In such cases, the error is not handled.

Resume also can be used on its own, outside the **On Error** statement. When **Resume** is used this way, Visual Basic returns control to the statement that caused the error. You generally use **Resume** after an error handler corrects the error.

Visual Basic also provides the **Resume Next** statement, which directs control to the line immediately following the line of code that caused the error. You might use **Resume Next** for cases in which an error will not cause your application to stop working. You might also use it if an error will not change the expected results of your subroutine.

Another variation on the **Resume** statement is **Resume Line**, which is similar to **On Error GoTo Line**. **Resume Line** passes control to a line you specify in the *line* argument. You can use **Resume Line** only within an error handler.

> **Note** When debugging your code, you must disable the **On Error Resume Next** statement.

On Error GoTo 0

The **On Error GoTo 0** statement disables any error handler in the current procedure. If you do not include an **On Error GoTo 0** statement, the error handler is still disabled when the procedure containing the exception handler ends.

> **Note** The **On Error GoTo 0** statement is not meant to specify line 0 as the start of the error-handling code, even if the procedure contains a line numbered 0.

On Error GoTo -1

The **On Error GoTo -1** statement disables any exception handlers in the current procedure. If you do not include an **On Error GoTo -1** statement, the exception is automatically disabled when its procedure ends.

> **Note** The **On Error GoTo -1** statement is not meant to specify line -1 as the start of the error-handling code, even if the procedure contains a line numbered -1.

Unstructured Exception Handler Example

In the following code, the exception handler is named `DivideByZero` and handles a specific error — that of attempting to divide by zero. If a different error occurs, Visual Basic raises a run-time error and stops the application.

```
Sub ErrorTest ()
' Declare variables.
   Dim x As Integer, y As Integer, z As Integer
   ' The exception handler is named "DivideByZero".
   On Error GoTo DivideByZero
   ' The main part of the code, which might cause an error.
   x = 2
   y = 0
   z = x \ y

   ' This line disables the exception handler.
   On Error GoTo 0
      Console.WriteLine(x & "/" & y & " = " & z)

   ' Exit the subroutine before the error-handling code.
   ' Failure to do so can create unexpected results.
   Exit Sub

   ' This is the exception handler, which deals with the error.
   DivideByZero:
   ' Include a friendly message to let the user know what is happening.
   Console.WriteLine("You have attempted to divide by zero!")

   ' Provide a solution to the error.
   y = 2

   ' The Resume statement returns to the point at which
   ' the error first occurred, so the application
   ' can continue to run.
   Resume

End Sub
```

The Err Object | Introduction to Exception Handling | Types of Errors | Structured Exception Handling | End Statement | Err Object (Language Reference) | Exit Statement | LastDllError Property | On Error Statement | Resume Statement

The Err Object

To write error-handling code, you need to know which error occurred. You can find this out by using the **Err** Object.

The **Err** object contains properties whose values are determined by the error that just occurred. The **Number** property contains the cause of the error, and the **Description** property contains a text message that describes the error in detail. **Helpfile** and **HelpContext** allow you to display a related help file when a user presses the **Help** button or the F1 key. **LastDLLError** displays the last DLL called, and whether or not the call was successful. **Source** specifies a string expression representing the object or application that generated the error.

Your error handler should test or save the relevant property values before any other error can occur. Your code can handle only a single error at a time, so you must deal with one before moving on to another.

> **Note** The **Err** Object can be used only with exceptions caught with the **On Error GoTo** statement.

Application-Specific Errors

In addition to handling errors generated by Visual Basic, you might also want to handle errors specific to your application.

If you create an object that accesses other objects, you should write code to deal with any unhandled errors the other objects pass back. If necessary, you can map the error codes in **Err.Number** to one of your own application-specific errors, and then pass it back to the caller of your object.

Reading from and Writing to the Registry

When programming in Visual Basic .NET, you can choose to access the registry via either the functions provided by Visual Basic .NET or the registry classes of the .NET Framework. The registry hosts information from the operating system as well as information from applications hosted on the machine. Working with the registry may compromise security by allowing inappropriate access to system resources or protected information.

Registry Class
: Presents an overview of the Registry class along with links to individual keys and members.

Reading from and Writing to the Registry Using the Microsoft.Win32 Namespace

Because you can use the GetSetting and **SaveSetting** functions to access keys only under **HKEY_CURRENT_USER\Software\VB and VBA Program Settings**, you may find them limiting. When that happens, you can use the **Registry** and **RegistryKey** classes in the Microsoft.Win32 namespace of the .NET Framework. For more information, see Registry Class and RegistryKey Class.

> **Security Note** It is more secure to write data to the current user (Microsoft.Win32.Registry.CurrentUser) than to the local computer (Microsoft.Win32.Registry.LocalMachine). A condition, that's typically referred to as "squatting," occurs when the key you are creating was previously created by another, possibly malicious, process. To prevent this from occurring, use the **RegistryKey.GetValue** method. It returns **Nothing** if the key does not already exist.

The **Registry** class supplies the base registry keys that can be used to access subkeys and their values. The base keys themselves are read-only. The following table lists and describes the seven keys exposed by the **Registry** class.

Key	Description
ClassesRoot	Defines the types of documents and the properties associated with those types.
CurrentConfig	Contains hardware configuration information that is not user-specific.
CurrentUser	Contains information about the current user preferences, such as environmental variables.
DynData	Contains dynamic registry data, such as that used by Virtual Device Drivers.
LocalMachine	Contains five subkeys (Hardware, SAM, Security, Software, and System) that hold the configuration data for the local machine.
PerformanceData	Contains performance information for software components.
Users	Contains information about the default user preferences.

The following example shows how to read a DWORD value from HKEY_CURRENT_USER:

```
Imports Microsoft.Win32
Dim regVersion As RegistryKey
Dim keyValue As String
keyValue = "Software\\Microsoft\\TestApp\\1.0"
regVersion = Registry.CurrentUser.OpenSubKey(keyValue, False)
Dim intVersion As Integer = 0
If (Not regVersion Is Nothing) Then
    intVersion = regVersion.GetValue("Version", 0)
    regVersion.Close()
End If
```

The following example reads, increments, and then writes a DWORD value to HKEY_CURRENT_USER:

```
Imports Microsoft.Win32
Dim regVersion As RegistryKey
regVersion =
Registry.CurrentUser.OpenSubKey("SOFTWARE\\Microsoft\\TestApp\\1.0", True)
If regVersion Is Nothing Then
    ' Key doesn't exist; create it.
    regVersion =
Registry.CurrentUser.CreateSubKey("SOFTWARE\\Microsoft\\TestApp\\1.0")
End If

Dim intVersion As Integer = 0
If (Not regVersion Is Nothing) Then
    intVersion = regVersion.GetValue("Version", 0)
    intVersion = intVersion + 1
    regVersion.SetValue("Version", intVersion)
    regVersion.Close()
End If
```

Reading from and Writing to the Registry Using Visual Basic Run-Time Functions

Visual Basic .NET offers four functions to access the registry. To use them, you must have Read and Write permission from the RegistryPermissionAccess Enumeration enumeration. Any code running with full trust (under the default security policy, this is any code installed on the user's local hard drive) has the necessary permissions to access the registry. For more information, see RegistryPermission Class.

Visual Basic .NET Function	Description
DeleteSetting	Deletes a section or key setting from an application's entry in th e registry.
GetSetting	Returns a key setting value from an application's entry in the re gistry.
GetAllSettings	Returns a list of key settings and their values from an applicatio n's entry in the registry.
SaveSetting	Creates or saves an application entry in the registry.

Note Section names cannot be returned via the **GetSetting** function.

If the key setting cannot be saved, an **ArgumentException** object is thrown. For more information on this exception, see ArgumentException Class.

The following example creates a registry key and two subkeys. It prints the first key's value and then prints the values of the first key as well as its subkeys. It then deletes the second subkey and prints the values of the first key and its subkeys to confirm the deletion of the second subkey.

```
' Create the first key.
SaveSetting("TestApp","Startup","FirstKey","First")
' Create the first subkey.
SaveSetting("TestApp","FirstKey","FirstSubKey","FirstSub")
' Create the second subkey.
SaveSetting("TestApp","FirstKey","SecondSubKey","SecondSub")
Try
   ' Write the first key's value.
   Console.WriteLine ((GetSetting("TestApp","Startup","FirstKey"))
   ' Write the first key as well as its two subkeys.
   Console.WriteLine (GetAllSettings("TestApp","Startup"))
   Catch e As ArgumentException
   Catch e As Exception
   Console.WriteLine (e.GetType.ToString)
   Finally
End Try
DeleteSetting("TestApp","FirstKey","SecondSubKey")
Try
   Console.WriteLine (GetSetting("TestApp","Startup","FirstKey"))
   Console.WriteLine (GetAllSettings("TestApp","Startup"))
   Catch e As ArgumentException
   Catch e As Exception
   Console.WriteLine (e.GetType.ToString)
   Finally
End Try
```

There is a limitation to using the built-in registry access functions: You can access only the registry keys under **HKEY_CURRENT_USER\Software\VB and VBA Program Settings**. To do so, you must be logged onto the system because the **HKEY_CURRENT_USER** registry key is not active until you log on to the system.

Registry settings that are to be accessed from a noninteractive process (such as mtx.exe) should be stored under either the **HKEY_LOCAL_MACHINE\Software** or the **HKEY_USER\DEFAULT\Software** registry keys.

Typographic and Code Conventions

Visual Basic documentation uses the following typographic and code conventions.

Typographic Conventions

Convention	Description
Sub, **If**, **ChDir**, **Print**, **True**, **Debug**	Words in bold with initial letter capitalized indicate language-specific keywords.
Setup	Words you are instructed to type appear in bold.
object, *varname*, *arglist*	Italic letters indicate placeholders for information you supply.
[*expressionlist*]	In syntax, items inside brackets are optional.
{ **Public** | **Private** }	In syntax, braces and a vertical bar indicate a mandatory choice between two or more items. You must choose one, and only one, of the items.
[**Protected** | **Friend**]	In syntax, a vertical bar separates alternative options. Within brackets, the alternatives are not exclusive. Within braces, the alternatives are exclusive.
[{ **ByRef** | **ByVal** }]	In syntax, brackets surrounding items within braces indicate that no more than one item may be included, and the items may also be omitted entirely.
$membname_1$, $membname_2$, $membname_3$	Subscripts differentiate multiple instances of the same placeholder.
$membname_1$ ... $membname_n$	In syntax, ellipses indicate an indefinite number of items of the kind immediately preceding the ellipses. In code, ellipses signify code omitted for the sake of clarity.
ESC, ENTER	Words in capital letters indicate key names and key sequences.
ALT+F1, CTRL+R	A plus sign (+) between key names indicates a combination of keys. For example, ALT+F1 means hold down the ALT key while pressing the F1 key.

Code Conventions

Sample code	Description
`MyString = "Hello, world!"`	This font is used for code, variables, and error message text.
`' This is a comment.`	An apostrophe (') introduces code comments.

`MyVar = "This is an " _`
`& "example" _`
`& " of how to continue code."`
	A space followed by an underscore (_) at the end of line continues a line of code.

Visual Basic Language Keywords

The following table contains a listing of the Visual Basic .NET language keywords. All language keywords are reserved.

AddHandler	AddressOf	Alias	And
AndAlso	Ansi	As	Assembly
Auto	Boolean	ByRef	Byte
ByVal	Call	Case	Catch
CBool	CByte	CChar	CDate
CDec	CDbl	Char	CInt
Class	CLng	CObj	Const
CShort	CSng	CStr	CType
Date	Decimal	Declare	Default
Delegate	Dim	DirectCast	Do
Double	Each	Else	ElseIf
End	Enum	Erase	Error
Event	Exit	False	Finally
For	Friend	Function	Get
GetType	**GoSub**	GoTo	Handles
If	Implements	Imports	In
Inherits	Integer	Interface	Is
Let	Lib	Like	Long
Loop	Me	Mod	Module
MustInherit	MustOverride	MyBase	MyClass
Namespace	New	Next	Not
Nothing	NotInheritable	NotOverridable	Object
On	Option	Optional	Or
OrElse	Overloads	Overridable	Overrides
ParamArray	Preserve	Private	Property
Protected	Public	RaiseEvent	ReadOnly
ReDim	REM	RemoveHandler	Resume
Return	Select	Set	Shadows
Shared	Short	Single	Static
Step	Stop	String	Structure
Sub	SyncLock	Then	Throw
To	True	Try	TypeOf
Unicode	Until	**Variant**	When
While	With	WithEvents	WriteOnly
Xor	#Const	#ExternalSource	#If...Then...#Else
#Region	-	&	&=
*	*=	/	/=
\	\=	^	^=
+	+=	=	-=

Note **GoSub**, **Let**, and **Variant** are retained as keywords, although they are no longer used in Visual Basic .NET.

Visual Basic Run-Time Library Members

The **Microsoft.VisualBasic** namespace contains the classes and modules that constitute the Visual Basic .NET run-time library. The library provides functions, methods, and properties you can use in your code. Each module and class represents a particular category of functionality.

Microsoft.VisualBasic.Collection Class

Add	Count	GetEnumerator	Item
Remove			

Microsoft.VisualBasic.ComClassAttribute Class

ClassID	EventID	InterfaceID	InterfaceShadows

Microsoft.VisualBasic.Conversion Module

ErrorToString	Fix	Hex	Int
Oct	Str	Val	

Microsoft.VisualBasic.DateAndTime Module

DateAdd	DateDiff	DatePart	DateSerial
DateString	DateValue	Day	Hour
Minute	Month	MonthName	Now
Second	TimeOfDay	Timer	TimeSerial
TimeString	TimeValue	Today	WeekDay
WeekDayName	Year		

Microsoft.VisualBasic.ErrObject Class

Clear	Description	Erl	GetException
HelpContext	HelpFile	LastDLLError	Number
Raise	Source		

Microsoft.VisualBasic.FileSystem Module

ChDir	ChDrive	CurDir	Dir
EOF	FileAttr	FileClose	FileCopy
FileDateTime	FileGet	FileGetObject	FileLen
FileOpen	FilePut	FilePutObject	FileWidth
FreeFile	GetAttr	Input	InputString
Kill	LineInput	Loc	Lock
LOF	MkDir	Print	PrintLine
Rename	Reset	RmDir	Seek
SetAttr	SPC	TAB	Unlock
Write	WriteLine		

Microsoft.VisualBasic.Financial Module

DDB	FV	IPmt	IRR
MIRR	NPer	NPV	Pmt
PPmt	PV	Rate	SLN
SYD			

Microsoft.VisualBasic.Globals Module

ScriptEngine	ScriptEngineBuildVersion	ScriptEngineMajorVersion	ScriptEngineMinorVersion

Microsoft.VisualBasic.Information Module

Err	IsArray	IsDate	IsDBNull
IsError	IsNothing	IsNumeric	IsReference
LBound	QBColor	RGB	SystemTypeName
TypeName	UBound	VarType	VbTypeName

Microsoft.VisualBasic.Interaction Module

AppActivate	Beep	CallByName	Choose
Command	CreateObject	DeleteSetting	Environ
GetAllSettings	GetObject	GetSetting	IIf
InputBox	MsgBox	Partition	SaveSetting
Shell	Switch		

Microsoft.VisualBasic.Strings Module

Asc	AscW	Chr	ChrW
Filter	Format	FormatCurrency	FormatDateTime
FormatNumber	FormatPercent	GetChar	InStr
InStrRev	Join	LCase	Left
Len	LSet	LTrim	Mid
Replace	Right	RSet	RTrim
Space	Split	StrComp	StrConv
StrDup	StrReverse	Trim	UCase

Microsoft.VisualBasic.VBFixedArrayAttribute Class

Bounds	Length		

Microsoft.VisualBasic.VBFixedStringAttribute Class

Length			

Microsoft.VisualBasic.VbMath Module

Randomize	Rnd		

The Visual Basic .NET run-time library also provides constants and enumeration members you can use in your code. Each enumeration represents a particular category of functionality. See Constants and Enumerations for more information.

Visual Basic Runtime Namespace in Visual Studio | Constants and Enumerations | Visual Basic Language Keywords | Keywords and Members By Task

Keywords and Members by Task

Visual Basic language keywords and run-time library members are organized by purpose and use.

Category	Description
Arrays	Creating, defining, and using arrays.
Collections	Using collections.
Compiler Directives	Controlling compiler behavior.
Control Flow	Looping and controlling procedure flow.
Conversion	Converting numbers and data types.
Data Types	Data types and object subtypes.
Dates and Times	Converting and using date and time expressions.
Directories and Files	Controlling the file system and processing files.
Errors	Trapping and returning error values.
Financial	Performing financial calculations.
Input and Output	Receiving input and displaying or printing output.
Information and Interaction	Starting other applications and processing events.
Math	Performing trigonometric and other mathematical calculations.
Operators	Comparing expressions and other operations.
Registry	Deleting, reading, and saving program settings.
String Manipulation	Manipulating strings and string type data.
Declarations and Constants	Declaring programming elements and defining constants.

Arrays Summary

Visual Basic language keywords and run-time library members are organized by purpose and use.

Action	Language element
Verify an array.	IsArray
Declare and initialize an array.	Dim, Private, Public, ReDim
Find the limits of an array.	LBound, UBound
Reinitialize an array	Erase, ReDim

Keywords and Members by Task | Visual Basic Language Keywords | Visual Basic Run-Time Library Members

Collection Object Summary

Visual Basic language keywords and run-time library members are organized by purpose and use.

Action	Language element
Create a **Collection** object.	Collection
Add an item to a collection.	Add
Remove an object from a collection.	Remove
Reference an item in a collection.	Item
Return a reference to an **IEnumerator** interface.	GetEnumerator

See Also

Keywords and Members by Task | Visual Basic Language Keywords | Visual Basic Run-Time Library Members

Compiler Directive Summary

Visual Basic language keywords and run-time library members are organized by purpose and use.

Action	Language element
Define a compiler constant.	#Const
Compile selected blocks of code.	#If...Then...#Else
Collapse and hide sections of code.	#Region
Indicate a mapping between source lines and text external to the source.	#ExternalSource

See Also

Keywords and Members by Task | Visual Basic Language Keywords | Visual Basic Run-Time Library Members

Control Flow Summary

Visual Basic language keywords and run-time library members are organized by purpose and use.

Action	Language element
Branch.	GoTo, On Error
Exit or pause the program.	End, Exit, Stop
Loop.	Do...Loop, For...Next, For Each...Next, While...End While, With
Make decisions.	Choose, If...Then...Else, Select Case, Switch
Use procedures.	Call, Function, Property, Sub

Keywords and Members by Task | Visual Basic Language Keywords | Visual Basic Run-Time Library Members

Conversion Summary

Visual Basic language keywords and run-time library members are organized by purpose and use.

Action	Language element
ANSI value to string.	Chr, ChrW
String to lowercase or uppercase.	Format, LCase, UCase
Date to serial number.	DateSerial, DateValue
Decimal number to other bases.	Hex, Oct
Number to string.	Format, Str
One data type to another.	CBool, CByte, CDate, CDbl, CDec, CInt, CLng, CSng, CShort, CStr, CType, Fix, Int
Date to day, month, weekday, or year .	Day, Month, Weekday, Year
Time to hour, minute, or second.	Hour, Minute, Second
String to ASCII value.	Asc, AscW
String to number.	Val
Time to serial number.	TimeSerial, TimeValue

See Also

Keywords and Members by Task | Visual Basic Language Keywords | Visual Basic Run-Time Library Members

Data Types Summary

Visual Basic language keywords and run-time library members are organized by purpose and use.

Action	Language element
Convert between data types.	CBool, CByte, CChar, CDate, CDbl, CDec, CInt, CLng, CObj, CShort, CSng, CStr, Fix, Int
Set intrinsic data types.	Boolean, Byte, Char, Date, Decimal, Double, Integer, Long, Object(default), Short, Single, String
Verify data types.	IsArray, IsDate, IsDbNull, IsError, IsNothing, IsNumeric, IsReference

See Also

Keywords and Members by Task | Visual Basic Language Keywords | Visual Basic Run-Time Library Members

Dates and Times Summary

Visual Basic language keywords and run-time library members are organized by purpose and use.

Action	Language element
Get the current date or time.	Now, Today, TimeOfDay
Perform date calculations.	DateAdd, DateDiff, DatePart
Return a date.	DateSerial, DateValue, MonthName, WeekDayName
Return a time.	TimeSerial, TimeValue
Set the date or time.	DateString, TimeOfDay, TimeString, Today
Time a process.	Timer

See Also

Keywords and Members by Task | Visual Basic Language Keywords | Visual Basic Run-Time Library Members

Declarations and Constants Summary

Visual Basic language keywords and run-time library members are organized by purpose and use.

Action	Language element
Assign a value.	Get, Property
Declare variables or constants.	Const, Dim, Private, Protected, Public, Shadows, Shared, Static
Declare a class, delegate, enumeration, module, namespace, or structure.	Class, Delegate, Enum, Module, Namespace, Structure
Create objects.	CreateObject, GetObject, New
Get information about an object.	GetType, IsArray, IsDate, IsDbNull, IsError, IsNothing, IsNumeric, IsReference, SystemTypeName, TypeName, VarType, VbTypeName
Refer to the current object.	Me
Require explicit variable declarations.	Option Explicit, Option Strict
Handle events.	AddHandler, Event, RaiseEvent, RemoveHandler
Implement inheritance.	Inherits, MustInherit, MustOverride, MyBase, MyClass, New, NotInheritable, NotOverridable, Overloads, Overridable, Overrides

Keywords and Members by Task | Visual Basic Language Keywords | Visual Basic Run-Time Library Members

Directories and Files Summary

Visual Basic language keywords and run-time library members are organized by purpose and use.

Action	Language element
Change a directory or folder.	ChDir
Change the drive.	ChDrive
Copy a file.	FileCopy
Make a directory or folder.	MkDir
Remove a directory or folder.	RmDir
Rename a file, directory, or folder.	Rename
Return the current path.	CurDir
Return a file's date/time stamp.	FileDateTime
Return file, directory, or label attributes.	GetAttr
Return a file's length.	FileLen
Return a file's name or volume label.	Dir
Set attribute information for a file.	SetAttr

Keywords and Members by Task | Visual Basic Language Keywords | Visual Basic Run-Time Library Members

Errors Summary

Visual Basic language keywords and run-time library members are organized by purpose and use.

Action	Language element
Generate run-time errors.	Clear, Error, Raise
Get exceptions.	GetException
Provide error information.	Err
Trap errors during run time.	On Error, Resume, Try...Catch...Finally
Provide line number of error.	Erl
Provide system error code.	LastDLLError

See Also

Keywords and Members by Task | Visual Basic Language Keywords | Visual Basic Run-Time Library Members

Financial Summary

Visual Basic language keywords and run-time library members are organized by purpose and use.

Action	Language element
Calculate depreciation.	DDB, SLN, SYD
Calculate future value.	FV
Calculate interest rate.	Rate
Calculate internal rate of return.	IRR, MIRR
Calculate number of periods.	NPer
Calculate payments.	IPmt, Pmt, PPmt
Calculate present value.	NPV, PV

See Also

Keywords and Members by Task | Visual Basic Language Keywords | Visual Basic Run-Time Library Members

Input and Output Summary

Visual Basic language keywords and run-time library members are organized by purpose and use.

Action	Language element
Access or create a file.	FileOpen
Close files.	FileClose, Reset
Control output appearance.	Format, Print, Spc, Tab, FileWidth
Copy a file.	FileCopy
Get information about a file.	EOF, FileAttr, FileDateTime, FileLen, FreeFile, GetAttr, Loc, LOF, Seek
Manage files.	Dir, Kill, Lock, Unlock
Read from a file.	FileGet, FileGetObject, Input, InputString, LineInput
Return length of a file.	FileLen
Set or get file attributes.	FileAttr, GetAttr, SetAttr
Set read-write position in a file.	Seek
Write to a file.	FilePut, FilePutObject, Print, Write

See Also

Keywords and Members by Task | Visual Basic Language Keywords | Visual Basic Run-Time Library Members

Math Summary

Visual Basic language keywords and run-time library members are organized by purpose and use.

Action	Language element
Derive trigonometric functions.	Atn, Cos, Sin, Tan
General calculations.	Exp, Log, Sqr
Generate random numbers.	Randomize, Rnd
Get absolute value.	Abs
Get the sign of an expression.	Sgn
Perform numeric conversions.	Fix, Int

See Also

Keywords and Members by Task | Visual Basic Language Keywords | Visual Basic Run-Time Library Members

Derived Math Functions

The following is a list of non-intrinsic math functions that can be derived from the intrinsic math functions:

Function	Derived equivalents
Secant (Sec(x))	1 / **Cos(**x**)**
Cosecant (Csc(x))	1 / **Sin(**x**)**
Cotangent (Ctan(x))	1 / **Tan(**x**)**
Inverse sine (Asin(x))	**Atan(**x / **Sqrt(**-x * x + 1**))**
Inverse cosine (Acos(x))	**Atan(**-x / **Sqrt(**-x * x + 1**))** + 2 * **Atan(**1**)**
Inverse secant (Asec(x))	2 * **Atan(**1**) – Atan(Sign(**x**)** / **Sqrt(**x * x **–** 1**))**
Inverse cosecant (Acsc(x))	**Atan(Sign(**x**)** / **Sqrt(**x * x **–** 1**))**
Inverse cotangent (Acot(x))	2 * **Atan(**1**)** - **Atan(**x**)**
Hyperbolic sine (Sinh(x))	(**Exp(**x**) – Exp(**-x**)**) / 2
Hyperbolic cosine (Cosh(x))	(**Exp(**x**)** + **Exp(**-x**)**) / 2
Hyperbolic tangent (Tanh(x))	(**Exp(**x**) – Exp(**-x**)**) / (**Exp(**x**)** + **Exp(**-x**)**)
Hyperbolic secant (Sech(x))	2 / (**Exp(**x**)** + **Exp(**-x**)**)
Hyperbolic cosecant (Csch(x))	2 / (**Exp(**x**) – Exp(**-x**)**)
Hyperbolic cotangent (Coth(x))	(**Exp(**x**)** + **Exp(**-x**)**) / (**Exp(**x**) – Exp(**-x**)**)
Inverse hyperbolic sine (Asinh(x))	**Log(**x + **Sqrt(**x * x + 1**))**
Inverse hyperbolic cosine (Acosh(x))	**Log(**x + **Sqrt(**x * x **–** 1**))**
Inverse hyperbolic tangent (Atanh(x))	**Log(**(1 + x) / (1 – x)**)** / 2
Inverse hyperbolic secant (AsecH(x))	**Log(**(**Sqrt(**-x * x + 1**)** + 1) / x**)**
Inverse hyperbolic cosecant (Acsch(x))	**Log(**(**Sign(**x**)** * **Sqrt(**x * x + 1**)** + 1) / x**)**
Inverse hyperbolic cotangent (Acoth(x))	**Log(**(x + 1) / (x – 1)**)** / 2

String Manipulation Summary

Visual Basic language keywords and run-time library members are organized by purpose and use.

Action	Language element
Compare two strings.	StrComp
Convert strings.	StrConv
Reverse a string.	InStrRev, StrReverse
Convert to lowercase or uppercase.	Format, LCase, UCase
Create a string of repeating characters.	Space, StrDup
Find the length of a string.	Len
Format a string.	Format, FormatCurrency, FormatDateTime, FormatNumber, FormatPercent
Manipulate strings.	InStr, Left, LTrim, Mid, Right, RTrim, Trim
Set string comparison rules.	Option Compare
Work with ASCII and ANSI values.	Asc, AscW, Chr, ChrW
Replace a specified substring.	Replace
Return a filter-based string array.	Filter
Return a specified number of substrings.	Split, Join

Visual Basic .NET Attributes

In This Section

COMClassAttribute Class

VBFixedArrayAttribute Class

VBFixedStringAttribute Class

Related Sections

Attributes (Conceptual)

ComClassAttribute Class

The **ComClassAttribute** attribute instructs the compiler to add metadata that allows a class to be exposed as a COM object.

```
<System.AttributeUsage(System.AttributeTargets.Class, _
   Inherited := False, AllowMultiple := False)> _
Public NotInheritable Class ComClassAttribute
   Inherits System.Attribute
```

Remarks

Use **ComClassAttribute** to simplify the process of creating COM components from Visual Basic .NET. COM objects are considerably different from .NET assemblies, and without the **ComClassAttribute**, you need to follow a number of steps to generate a COM object from Visual Basic .NET. For classes marked with **ComClassAttribute**, the compiler performs many of these steps automatically.

Example

To run this example, create a new **Class Library** application and add the following code to a class module.

```
<ComClass(ComClass1.ClassId, ComClass1.InterfaceId, ComClass1.EventsId)> _
Public Class ComClass1
   ' Use the Region directive to define a section named COM Guids.
#Region "COM GUIDs"
   ' These  GUIDs provide the COM identity for this class
   ' and its COM interfaces. You can generate
   ' these guids using guidgen.exe
    Public Const ClassId As String = "7666AC25-855F-4534-BC55-27BF09D49D46"
    Public Const InterfaceId As String = "54388137-8A76-491e-AA3A-853E23AC1217"
    Public Const EventsId As String = "EA329A13-16A0-478d-B41F-47583A761FF2"
#End Region

   Public Sub New()
      MyBase.New()
   End Sub

   Function AddNumbers(ByVal X As Integer, ByVal Y As Integer)
      AddNumbers = X + Y
   End Function
End Class
```

> **Note** This attribute simplifies the creation of COM objects. To create a COM object, you must compile the project with the **Register for COM Interop** option selected in the **Build** section of the **Configuration Properties** dialog.

Requirements

Namespace: Microsoft.VisualBasic

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Attributes | Applying Interop Attributes | ComClassAttribute Class Members | Walkthrough: Creating COM Objects with Visual Basic .NET | VBFixedArrayAttribute Class | VBFixedStringAttribute Class | Attributes Used in Visual Basic .NET | System.Runtime.InteropServices Namespace | Declaring Variables for Random File Access

ComClassAttribute Class Members

Properties

ClassID Property	Contains a class ID used to uniquely identify the class.
EventID Property	Contains an event ID used to uniquely identify the event.
InterfaceID Property	Contains an interface ID used to uniquely identify the interface.
InterfaceShadows Property	Indicates that a generated COM interface name shadows another member of the class or base class.

Constructor

ComClassAttribute Constructor	Initializes a new instance of the **ComClassAttribute** class.

Requirements

Namespace: Microsoft.VisualBasic

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Attributes | Walkthrough: Creating COM Objects with Visual Basic .NET | Applying Interop Attributes | VBFixedArrayAttribute Class | VBFixedStringAttribute Class | ComClassAttribute Class | Shadows | Attributes Used in Visual Basic .NET | System.Runtime.InteropServices Namespace

ComClassAttribute Constructor

Initializes a new instance of the **ComClassAttribute** class.

```
Public Sub New()
```

-or-

```
Public Sub New( _
   ByVal _ClassID As String _
)
```

-or-

```
Public Sub New( _
   ByVal _ClassID As String, _
   ByVal _InterfaceID As String _
)
```

-or-

```
Public Sub New( _
   ByVal _ClassID As String, _
   ByVal _InterfaceID As String, _
   ByVal _EventID As String _
)
```

Parameters

_ClassID
Initializes the value of the **ClassID** property that is used to uniquely identify a class.
_InterfaceID
Initializes the value of the **InterfaceID** property that is used to uniquely identify an interface.
_EventID
Initializes the value of the **EventID** property that is used to uniquely identify an event.

Remarks

The constructor for the **ComClassAttribute** class allows you to set the **ClassID**, **InterfaceID**, or **EventID** properties when applying the **ComClassAttribute** to a class.

Requirements

Namespace: Microsoft.VisualBasic

Class: ComClassAttribute

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Attributes | ComClassAttribute Class | Attributes Used in Visual Basic .NET |
Walkthrough: Creating COM Objects with Visual Basic .NET | System.Runtime.InteropServices Namespace |
Object Lifetime: How Objects Are Created and Destroyed

ComClassAttribute.ClassID Property

Gets a class ID used to uniquely identify a class.

```
Public ReadOnly Property ClassID As String
```

Property Value

Read only. A string that can be used by the compiler to uniquely identify the class when a COM object is created.

Remarks

The constructor sets this property when the **ComClassAttribute** is applied to a class.

Requirements

Namespace: Microsoft.VisualBasic

Class: ComClassAttribute

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Attributes | ComClassAttribute Class | Attributes Used in Visual Basic .NET | System.Runtime.InteropServices Namespace

ComClassAttribute.EventID Property

Gets an event ID used to uniquely identify an event.

```
Public ReadOnly Property EventID As String
```

Property Value

Read only. A string that can be used by the compiler to uniquely identify an event for the class when a COM object is created.

Remarks

The constructor sets this property when the **ComClassAttribute** is applied to a class.

Requirements

Namespace: Microsoft.VisualBasic

Class: ComClassAttribute

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Attributes | ComClassAttribute Class | Attributes Used in Visual Basic .NET | System.Runtime.InteropServices Namespace

ComClassAttribute.InterfaceID Property

Gets an interface ID used to uniquely identify an interface.

```
Public ReadOnly Property InterfaceID As String
```

Property Value

Read only. A string that can be used by the compiler to uniquely identify an interface for the class when a COM object is created.

Remarks

The constructor sets this property when the **ComClassAttribute** is applied to a class.

Requirements

Namespace: Microsoft.VisualBasic

Class: ComClassAttribute

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Attributes | ComClassAttribute Class | Attributes Used in Visual Basic .NET | System.Runtime.InteropServices Namespace

ComClassAttribute.InterfaceShadows Property

Indicates that the COM interface name shadows another member of the class or base class.

```
Public Property InterfaceShadows As Boolean
```

Property Value

A **Boolean** value that indicates that the COM interface name shadows another member of the class or base class.

Remarks

Shadowing is when a member uses the same name as another member.

Requirements

Namespace: Microsoft.VisualBasic

Class: ComClassAttribute

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Attributes | Shadowing | ComClassAttribute Class | Attributes Used in Visual Basic .NET | System.Runtime.InteropServices Namespace

VBFixedArrayAttribute Class

Indicates that an array in a structure or non-local variable should be treated as a fixed length array.

```
<System.AttributeUsage(System.AttributeTargets.Field, _
   Inherited := False, AllowMultiple := False)> _
Public NotInheritable Class VBFixedArrayAttribute
   Inherits System.Attribute
```

Remarks

Visual Basic .NET arrays are of variable length by default. This attribute is useful when using Visual Basic .NET file input and output functions, such as **FileGet** and **FilePut**, and API calls that require fixed length arrays.

Example

```
    Structure Book
        <VBFixedArray(4)> Public Chapter() As Integer
    End Structure

    Sub WriteData()
        Dim FileNum As Integer = FreeFile()
        Dim MyBook As Book
        ReDim MyBook.Chapter(4)
        ' Add code to populate the array.
        MyBook.Chapter(0) = 1
        MyBook.Chapter(1) = 2
        MyBook.Chapter(2) = 3
        MyBook.Chapter(3) = 4
        MyBook.Chapter(4) = 5
        ' Write the array to a file.
        FileOpen(FileNum, "C:\testfile", OpenMode.Binary, _
                 OpenAccess.Write, OpenShare.Default)
        FilePut(FileNum, MyBook) ' Write data.
        FileClose(FileNum)
    End Sub
```

Note The **VBFixedArrayAttribute** is informational and does not allocate any storage. The purpose of this attribute is to modify how arrays in structures and non-local variables are used by methods or API calls that recognize the **VBFixedArrayAttribute**. Keep in mind that this attribute does not convert a variable length array to a fixed array and that you must still allocate array storage using **Dim** or **ReDim** statements.

Requirements

Namespace: Microsoft.VisualBasic

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Attributes | VBFixedArrayAttribute Class Members | VBFixedStringAttribute Class | MarshalAsAttribute Class | ComClassAttribute Class | Declaring Variables for Random File Access | XML and SOAP Serialization | FileGet Function | FilePut Function | FileOpen Function

VBFixedArrayAttribute Class Members

Properties

Bounds	Returns the bounds of the array.
Length	Returns the size of the array.

Constructor

VBFixedArrayAttribute Constructor	Initializes the bounds of a fixed-sized array.

Requirements

Namespace: Microsoft.VisualBasic

Class: VBFixedArrayAttribute

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Attributes | VBFixedStringAttribute Class | ComClassAttribute Class | MarshalAsAttribute Class | Attributes Used in Visual Basic .NET | Declaring Variables for Random File Access

VBFixedArrayAttribute Constructor

Initializes the value of the **Bounds** property.

```
Public Sub New( _
   ByVal UpperBound1 As Integer, _
   )
```

-or-

```
Public Sub New( _
   ByVal UpperBound1 As Integer, _
   ByVal UpperBound2 As Integer, _
   )
```

Parameters

UpperBound1
Initializes the value of upper field, which represents the size of the first dimension of the array.
UpperBound2
Initializes the value of upper field, which represents the size of the second dimension of the array.

Remarks

The constructor runs when the **VBFixedArrayAttribute** attribute is applied to an array.

Requirements

Namespace: Microsoft.VisualBasic

Class: VBFixedArrayAttribute

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Attributes | VBFixedStringAttribute Class | ComClassAttribute Class | Attributes Used in Visual Basic .NET | MarshalAsAttribute Class | Declaring Variables for Random File Access | Object Lifetime: How Objects Are Created and Destroyed

VBFixedArrayAttribute.Bounds Property

Returns the bounds of the array.

```
Public ReadOnly Property Bounds() As Integer()
```

Property Value

Contains an integer array that represents the bounds of the array.

Remarks

The constructor sets this property when the **VBFixedArrayAttribute** is applied to an array.

Requirements

Namespace: Microsoft.VisualBasic

Class: VBFixedArrayAttribute

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Attributes | VBFixedStringAttribute Class | ComClassAttribute Class | MarshalAsAttribute Class | Attributes Used in Visual Basic .NET | Declaring Variables for Random File Access

VBFixedArrayAttribute.Length Property

Returns the size of the array.

```
Public ReadOnly Property Length As Integer
```

Property Value

Contains an integer that represents the number of elements in the array.

Remarks

The constructor sets this property when the **VBFixedArrayAttribute** is applied to an array.

Requirements

Namespace: Microsoft.VisualBasic

Class: VBFixedArrayAttribute

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Attributes | VBFixedStringAttribute Class | ComClassAttribute Class | MarshalAsAttribute Class | Attributes Used in Visual Basic .NET | Declaring Variables for Random File Access

VBFixedStringAttribute Class

Indicates that a string should be treated as if it were fixed length.

```
<System.AttributeUsage(System.AttributeTargets.Field, _
   Inherited := False, AllowMultiple := False)> _
Public NotInheritable Class VBFixedStringAttribute
   Inherits System.Attribute
```

Remarks

Visual Basic .NET strings are of variable length by default. This attribute is useful when using Visual Basic .NET file input and output functions, such as **FileGet** and **FilePut** that require fixed length strings.

Example

```
Structure Person
   Public ID As Integer
   Public MonthlySalary As Decimal
   Public LastReviewDate As Long
   <VBFixedString(15)> Public FirstName As String
   <VBFixedString(15)> Public LastName As String
   <VBFixedString(15)> Public Title As String
   <VBFixedString(150)> Public ReviewComments As String
End Structure
```

> **Note** The **VBFixedStringAttribute** is informational and cannot be used to convert a variable length string to a fixed string. The purpose of this attribute is to modify how strings in structures and non-local variables are used by methods or API calls that recognize the **VBFixedStringAttribute**. Keep in mind that this attribute does not change the actual length of the string itself.

Smart Device Developer Notes

This class is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Attributes | VBFixedStringAttribute Class Members | VBFixedArrayAttribute Class | StringBuilder Class | MarshalAsAttribute Class | ComClassAttribute Class | Attributes Used in Visual Basic .NET | Declaring Variables for Random File Access | FileGet Function | FilePut Function | FileOpen Function

VBFixedStringAttribute Class Members

Fields

VBFixedStringAttribute.Length	Gets the length of the string.

Constructor

VBFixedStringAttribute Constructor	Initializes the value of the **SizeConst** field.

Smart Device Developer Notes

This class is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Attributes | VBFixedArrayAttribute Class | VBFixedStringAttribute Class | StringBuilder Class | MarshalAsAttribute Class | ComClassAttribute Class | Attributes Used in Visual Basic .NET | Declaring Variables for Random File Access

VBFixedStringAttribute Constructor

Initializes the value of the **SizeConst** field.

```
Public Sub New( _
   ByVal Length As Integer _
)
```

Parameters

Length
The length of the fixed string.

Remarks

The constructor runs when the **VBFixedStringAttribute** attribute is applied to a string.

Smart Device Developer Notes

This constructor is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Class: VBFixedStringAttribute

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Attributes | VBFixedStringAttribute Class | StringBuilder Class | MarshalAsAttribute Class | Attributes Used in Visual Basic .NET | Object Lifetime: How Objects Are Created and Destroyed | Declaring Variables for Random File Access

VBFixedStringAttribute.Length Property

Gets the length of the string.

```
Public ReadOnly Property Length As Integer
```

Property Value

Returns the length of the string.

Remarks

The constructor for this attribute sets this property when the **VBFixedStringAttribute** is applied to a string.

Smart Device Developer Notes

This property is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Class: VBFixedStringAttribute

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

AppWinStyle Enumeration

When you issue **Shell** commands, you can use the following enumeration members in your code in place of the actual values.

AppWinStyle Enumeration Members

The *Style* argument takes the following **AppWinStyle** enumeration members:

Member	Constant	Description
Hide	**vbHide**	Window is hidden and focus is passed to the hidden window.
NormalFocus	**vbNormalFocus**	Window has focus and is restored to its original size and position.
MinimizedFocus	**vbMinimizedFocus**	Window is displayed as an icon with focus.
MaximizedFocus	**vbMaximizedFocus**	Window is maximized with focus.
NormalNoFocus	**vbNormalNoFocus**	Window is restored to its most recent size and position. The currently active window remains active.
MinimizedNoFocus	**vbMinimizedNoFocus**	Window is displayed as an icon. The currently active window remains active.

Requirements

Namespace: Microsoft.VisualBasic

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Intrinsic Constants and Enumerations | Shell Function

CallType Enumeration

When you call the **CallByName** function, you can use the following **CallType** enumeration members in your code in place of the actual values:

CallType Enumeration Members

The *UseCallType* argument takes the following **CallType** values:

Member	Constant	Description
Method	**vbMethod**	A method is being invoked.
Get	**vbGet**	A property value is being retrieved.
Set	**vbSet**	A property value is being determined.
Let	**vbLet**	An Object property value is being determined.

Smart Device Developer Notes

This enumeration is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Intrinsic Constants and Enumerations | CallByName Function | CallType Constant Changes in Visual Basic .NET

CompareMethod Enumeration

When you call comparison functions, you can use the **CompareMethod** enumeration in your code in place of the actual values.

CompareMethod Enumeration Members

The *Compare* argument takes the following **CompareMethod** enumeration members:

Member	Constant	Description
Binary	**vbBinaryCompare**	Performs a binary comparison.
Text	**vbTextCompare**	Performs a textual comparison.

Requirements

Namespace: Microsoft.VisualBasic

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Intrinsic Constants and Enumerations | Filter Function | InStr Function | InStrRev Function | Replace Function | Split Function | StrComp Function

DateFormat Enumeration

When you call the **DateValue** function, you can use the following enumeration members in your code in place of the actual values.

Member	Constant	Description
GeneralDate	**vbGeneralDate**	For real numbers, displays a date and time. If the number has no fractional part, displays only a date. If the number has no integer part, displays time only. Date and time display is determined by your computer's regional settings.
LongDate	**vbLongDate**	Displays a date using the long-date format specified in your computer's regional settings.
ShortDate	**vbShortDate**	Displays a date using the short-date format specified in your computer's regional settings.
LongTime	**vbLongTime**	Displays a time using the long-time format specified in your computer's regional settings.
ShortTime	**vbShortTime**	Displays a time using the short-time format specified in your computer's regional settings.

Note You can access your computer's regional settings by double-clicking the Regional Options icon, found in the Control Panel.

Requirements

Namespace: Microsoft.VisualBasic

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

DateValue Function

DateInterval Enumeration

When you call date-related functions, you can use enumeration members in your code in place of the actual values.

The **DateInterval** enumeration defines constants used with date-related functions to identify how date intervals are determined and formatted. The following table lists the **DateInterval** enumeration members.

Member	Description
DateInterval.Day	Day of month (1 through 31)
DateInterval.DayOfYear	Day of year (1 through 366)
DateInterval.Hour	Hour (1 through 24)
DateInterval.Minute	Minute (1 through 60)
DateInterval.Month	Month (1 through 12)
DateInterval.Quarter	Quarter of year (1 through 4)
DateInterval.Second	Second (1 through 60)
DateInterval.Weekday	Day of week (1 through 7)
DateInterval.WeekOfYear	Week of year (1 through 53)
DateInterval.Year	Year

Requirements

Namespace: Microsoft.VisualBasic

Assembly: Microsoft.VisualBasic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Intrinsic Constants and Enumerations | DateFormat Enumeration| DueDate Enumeration | DatePart Function | DateAdd Function | DateDiff Function

DueDate Enumeration

When you call date-related functions, you can use enumeration members in your code in place of the actual values.

The **DueDate** enumeration defines constants used to identify where a due date falls within a date interval. The following table lists the **DueDate** enumeration members.

Member	Description
DueDate.BegOfPeriod	Falls at the beginning of the date interval
DueDate.EndOfPeriod	Falls at the end of the date interval

Requirements

Namespace: Microsoft.VisualBasic

Assembly: Microsoft.VisualBasic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Intrinsic Constants and Enumerations | DateInterval Enumeration | DatePart Function| DateAdd Function | DateDiff Function

FileAttribute Enumeration

When you call the **Dir**, **GetAttr**, or **SetAttr** functions, you can use the **FileAttribute** enumeration in your code in place of the actual values.

FileAttribute Enumeration Members

The *Attributes* argument takes the following **FileAttribute** enumeration members:

Member	Constant	Description
Normal	**vbNormal**	Normal (default for **Dir** and **SetAttr**). No special characteristics apply to this file.
ReadOnly	**vbReadOnly**	Read only.
Hidden	**vbHidden**	Hidden.
System	**vbSystem**	System file.
Volume	**vbVolume**	Volume label.
Directory	**vbDirectory**	Directory or folder.
Archive	**vbArchive**	File has changed since last backup.

Smart Device Developer Notes

This enumeration is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Intrinsic Constants and Enumerations | Dir Function | GetAttr Function | SetAttr Function

FirstDayOfWeek Enumeration

When you call date-related functions, you can use the following enumeration members in your code in place of the actual values.

Some date-related functions take a *DayOfWeek* argument, a *WeekOfYear* argument, or both. The **FirstDayOfWeek** enumeration specifies the valid values for the *DayOfWeek* arguments, as well as the possible return values from the functions.

FirstDayOfWeek Enumeration Members

The *DayOfWeek* argument takes the following **FirstDayOfWeek** enumeration members:

Member	Constant	Description
System	**vbUseSystemDayOfWeek**	The first day of the week as specified in your system settings
Sunday	**vbSunday**	Sunday (default)
Monday	**vbMonday**	Monday
Tuesday	**vbTuesday**	Tuesday
Wednesday	**vbWednesday**	Wednesday
Thursday	**vbThursday**	Thursday
Friday	**vbFriday**	Friday
Saturday	**vbSaturday**	Saturday

Date-related functions also return **FirstDayOfWeek** values (except **System**).

Requirements

Namespace: Microsoft.VisualBasic

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Intrinsic Constants and Enumerations | FirstWeekOfYear Enumeration | DateFormat Enumeration | DateDiff Function | DatePart Function | Format Function | Weekday Function

FirstWeekOfYear Enumeration

When you call date-related functions, you can use the following enumeration members in your code in place of the actual values.

Some date-related functions take a *DayOfWeek* argument, a *WeekOfYear* argument, or both. The **FirstWeekOfYear** enumeration specifies the valid values for the *WeekOfYear* arguments, as well as the possible return values from the functions.

FirstWeekOfYear Enumeration Members

The *WeekOfYear* argument takes the following **FirstWeekOfYear** enumeration members:

Member	Constant	Description
System	**vbUseSystem**	The day of the week specified in your system settings as the first day of the week
Jan1	**vbFirstJan1**	The week in which January 1 occurs (default)
FirstFourDays	**vbFirstFourDays**	The first week that has at least four days in the new year
FirstFullWeek	**vbFirstFullWeek**	The first full week of the year

Requirements

Namespace: Microsoft.VisualBasic

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Intrinsic Constants and Enumerations | FirstDayOfWeek Enumeration | DateFormat Enumeration | DateDiff Function | DatePart Function | Format Function

MsgBoxResult Enumeration

When you call the **MsgBox** function, you can use the **MsgBoxResult** enumeration in your code in place of the actual values.

MsgBoxResult Enumeration Members

The **MsgBox** function returns the following **MsgBoxResult** enumeration values:

Member	Constant	Description
OK	**vbOK**	**OK** button was pressed.
Cancel	**vbCancel**	**Cancel** button was pressed.
Abort	**vbAbort**	**Abort** button was pressed.
Retry	**vbRetry**	**Retry** button was pressed.
Ignore	**vbIgnore**	**Ignore** button was pressed.
Yes	**vbYes**	**Yes** button was pressed.
No	**vbNo**	**No** button was pressed.

Requirements

Namespace: Microsoft.VisualBasic

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Intrinsic Constants and Enumerations | MsgBoxStyle Enumeration | MsgBox Function

MsgBoxStyle Enumeration

When you call the **MsgBox** function, you can use the **MsgBoxStyle** enumeration in your code in place of the actual values.

MsgBoxStyle Enumeration Members

The *Buttons* argument takes the following **MsgBoxStyle** enumeration members:

Member	Constant	Description
OKOnly	**vbOKOnly**	**OK** button only (default).
OKCancel	**vbOKCancel**	**OK** and **Cancel** buttons.
AbortRetryIgnore	**vbAbortRetryIgnore**	**Abort**, **Retry**, and **Ignore** buttons.
YesNoCancel	**vbYesNoCancel**	**Yes**, **No**, and **Cancel** buttons.
YesNo	**vbYesNo**	**Yes** and **No** buttons.
RetryCancel	**vbRetryCancel**	**Retry** and **Cancel** buttons.
Critical	**vbCritical**	Critical message.
Question	**vbQuestion**	Warning query.
Exclamation	**vbExclamation**	Warning message.
Information	**vbInformation**	Information message.
DefaultButton1	**vbDefaultButton1**	First button is default (default).
DefaultButton2	**vbDefaultButton2**	Second button is default.
DefaultButton3	**vbDefaultButton3**	Third button is default.
ApplicationModal	**vbApplicationModal**	Application modal message box (default).
SystemModal	**vbSystemModal**	System modal message box.
MsgBoxSetForeground	**vbMsgBoxSetForeground**	Foreground message box window.
MsgBoxRight	**vbMsgBoxRight**	Right-aligned text.
MsgBoxRtlReading	**vbMsgBoxRtlReading**	Right-to-left reading text (Hebrew and Arabic systems) .
MsgBoxHelp	**vbMsgBoxHelp**	Help text.

Requirements

Namespace: Microsoft.VisualBasic

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

OpenAccess Enumeration

When you call file access-related functions, you can use enumeration members in your code in place of the actual values.

The **OpenAccess** enumeration defines constants used to identify how a file can be accessed. The following table lists the **OpenAccess** enumeration members.

Member	Description
OpenAccess.Default	Read and write permitted. This is the default.
OpenAccess.Read	Read permitted.
OpenAccess.ReadWrite	Read and write permitted.
OpenAccess.Write	Write permitted.

Requirements

Namespace: Microsoft.VisualBasic

Assembly: Microsoft.VisualBasic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Intrinsic Constants and Enumerations | OpenAccess (Object Browser) | OpenMode Enumeration | OpenShare Enumeration

OpenMode Enumeration

When you call file access-related functions, you can use enumeration members in your code in place of the actual values.

The **OpenMode** enumeration defines constants used to set file access modes. The following table lists the **OpenMode** enumeration members.

Member	Description
OpenMode.Append	File opened to append to it
OpenMode.Binary	File opened for binary access
OpenMode.Input	File opened for write access
OpenMode.Output	File opened for read access
OpenMode.Random	File opened for random access

Requirements

Namespace: Microsoft.VisualBasic

Assembly: Microsoft.VisualBasic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Intrinsic Constants and Enumerations | OpenShare Enumeration | OpenMode (Object Browser) | OpenAccess Enumeration | Binary File Access | Random File Access

OpenShare Enumeration

When you call file access-related functions, you can use enumeration members in your code in place of the actual values.

The **OpenShare** enumeration defines constants that identify a file's sharing level. The following table lists the **OpenShare** enumeration members.

Member	Description
OpenShare.Default	Shared. This is the default.
OpenShare.LockRead	Other processes cannot read the file.
OpenShare.LockReadWrite	Other processes cannot read or write to the file.
OpenShare.LockWrite	Other processes cannot write to the file.
OpenShare.Shared	Any process can read or write to the file.

Requirements

Namespace: Microsoft.VisualBasic

Assembly: Microsoft.VisualBasic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Intrinsic Constants and Enumerations | OpenShare (Object Browser) | OpenAccess Enumeration | OpenMode Enumeration

Print and Display Constants

When you call print and display functions, you can use the following constants in your code in place of the actual values.

ControlChars Module Members

Member	Constant	Equivalent	Description
CrLf	**vbCrLf**	**Chr(**13**) + Chr(**10**)**	Carriage return/linefeed character combination.
Cr	**vbCr**	**Chr(**13**)**	Carriage return character.
Lf	**vbLf**	**Chr(**10**)**	Linefeed character.
NewLine	**vbNewLine**	**Chr(**13**) + Chr(**10**)**	New line character.
NullChar	**vbNullChar**	**Chr(**0**)**	Character having value 0.
na	**vbNullString**	String having value 0	Not the same as a zero-length string (""); used for calling external procedures.
na	**vbObjectError**	-2147221504	Error number. User-defined error numbers should be greater than this value. For example: `Err.Raise(Number) = vbObjectError + 1000`
Tab	**vbTab**	**Chr(**9**)**	Tab character.
Back	**vbBack**	**Chr(**8**)**	Backspace character.
FormFeed	**vbFormFeed**	**Chr(**12**)**	Not useful in Microsoft Windows.
VerticalTab	**vbVerticalTab**	**Chr(**11**)**	Not useful in Microsoft Windows.
Quote	na	**Chr(**34**)**	Quotation mark character (" or ') used to enclose values.

Requirements

Namespace: Microsoft.VisualBasic

Module: Constants

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

TriState Enumeration

When you call number-formatting functions, you can use the following enumeration members in your code in place of the actual values.

Constant	Value	Description
True	–1	True
False	0	False
UseDefault	–2	Default setting

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

FormatNumber Function | FormatCurrency Function | FormatPercent Function

VariantType Enumeration

When you call the **VarType** function, you can use enumeration members in your code in place of the actual values.

The **VariantType** enumeration defines constants used to identify possible **Variant** types. The following table lists the **VariantType** enumeration members.

Member	Constant	Description
VariantType.Array	**vbArray**	Array.
VariantType.Boolean	**vbBoolean**	**Boolean**. (**True** or **False**.)
VariantType.Byte	**vbByte**	**Byte**. (0 through 255.)
VariantType.Char	**vbChar**	**Char**. (0 through 65535.)
VariantType.Currency	**vbCurrency**	Currency.
VariantType.DataObject		DataObject.
VariantType.Date	**vbDate**	**Date**. (0:00:00 on January 1, 0001 through 11:59:59 PM on December 31, 9999.)
VariantType.Decimal	**vbDecimal**	**Decimal**. (0 through +/-79,228,162,514,264,337,593,543,950,335 with no decimal point; 0 through +/-7.9228162514264337593543950335 with 28 places to the right of the decimal; smallest non-zero number is +/-0.0000000000000000000000000001.)
VariantType.Double	**vbDouble**	**Double**. (-1.79769313486231E+308 through -4.94065645841247E-324 for negative values; 4.94065645841247E-324 through 1.79769313486231E+308 for positive values.)
VariantType.Empty	**vbEmpty**	Null reference.
VariantType.Error		
VariantType.Integer	**vbInteger**	**Integer**. (-2,147,483,648 through 2,147,483,647.)
VariantType.Long	**vbLong**	**Long**. (-9,223,372,036,854,775,808 through 9,223,372,036,854,775,807.)
VariantType.Null	**vbNull**	Null object.
VariantType.Object	**vbObject**	Any type can be stored in a variable of type **Object**.
VariantType.Short		**Short**. (-32,768 through 32,767.)
VariantType.Single	**vbSingle**	**Single**. (-3.402823E+38 through -1.401298E-45 for negative values; 1.401298E-45 through 3.402823E+38 for positive values.)
VariantType.String	**vbString**	**String**. (0 to approximately 2 billion Unicode characters.)
VariantType.UserDefinedType	**vbUserDefinedType**	User-defined type. Each member of the structure has a range determined by its data type and independent of the ranges of the other members.
VariantType.Variant	**vbVariant**	**Variant**.

Smart Device Developer Notes

This enumeration is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Assembly: Microsoft.VisualBasic .NET Runtime (in Microsoft.VisualBasic.dll)

VbStrConv Enumeration

When you call the **StrConv** function, you can use the following enumeration members in your code in place of the actual values.

VbStrConv Enumeration Members

The *Conversion* argument takes the following **VbStrConv** enumeration members:

Member	Constant	Description
UpperCase	**vbUpperCase**	Converts the string to uppercase characters.
LowerCase	**vbLowerCase**	Converts the string to lowercase characters.
ProperCase	**vbProperCase**	Converts the first letter of every word in the string to uppercase.
Wide	**vbWide**	Converts narrow (single-byte) characters in the string to wide (double-byte) characters. Applies to Asian locales.
Narrow	**vbNarrow**	Converts wide (double-byte) characters in the string to narrow (single-byte) characters. Applies to Asian locales.
Katakana	**vbKatakana**	Converts Hiragana characters in the string to Katakana characters. Applies to Japanese locale only.
Hiragana	**vbHiragana**	Converts Katakana characters in the string to Hiragana characters. Applies to Japanese locale only.
SimplifiedChinese	**vbSimplifiedChinese**	Converts the string to Simplified Chinese characters.
TraditionalChinese	**vbTraditionalChinese**	Converts the string to Traditional Chinese characters.
LinguisticCasing	**vbLinguisticCasing**	Converts the string from file system rules for casing to linguistic rules.

Smart Device Developer Notes

This enumeration is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Data Type Summary

The following table shows the Visual Basic .NET data types, their supporting common language runtime types, their nominal storage allocation, and their value ranges.

Visual Basic type	Common language runtime type structure	Nominal storage allocation	Value range
Boolean	**System.Boolean**	2 bytes	**True** or **False.**
Byte	**System.Byte**	1 byte	0 through 255 (unsigned).
Char	**System.Char**	2 bytes	0 through 65535 (unsigned).
Date	**System.DateTime**	8 bytes	0:00:00 on January 1, 0001 through 11:59:59 PM on December 31, 9999.
Decimal	**System.Decimal**	16 bytes	0 through +/-79,228,162,514,264,337,593,543,950,335 with no decimal point; 0 through +/-7.9228162514264337593543950335 with 28 places to the right of the decimal; smallest nonzero number is +/-0.0000000000000000000000000001 (+/-1E-28).
Double (double-precision floating-point)	**System.Double**	8 bytes	-1.79769313486231570E+308 through -4.94065645841246544E-324 for negative values; 4.94065645841246544E-324 through 1.79769313486231570E+308 for positive values.
Integer	**System.Int32**	4 bytes	-2,147,483,648 through 2,147,483,647.
Long (long integer)	**System.Int64**	8 bytes	-9,223,372,036,854,775,808 through 9,223,372,036,854,775,807.
Object	**System.Object** (class)	4 bytes	Any type can be stored in a variable of type **Object**.
Short	**System.Int16**	2 bytes	-32,768 through 32,767.
Single (single-precision floating-point)	**System.Single**	4 bytes	-3.4028235E+38 through -1.401298E-45 for negative values; 1.401298E-45 through 3.4028235E+38 for positive values.
String (variable-length)	**System.String** (class)	Depends on implementing platform	0 to approximately 2 billion Unicode characters.
User-Defined Type (structure)	(inherits from **System.ValueType**)	Depends on implementing platform	Each member of the structure has a range determined by its data type and independent of the ranges of the other members.

Note For strings containing text, use the **StrConv** function to convert from one text format to another.

Memory Consumption

When you declare an elementary data type, it is not safe to assume that its memory consumption is the same as its nominal storage allocation. The common language runtime assigns storage based on the characteristics of the platform on which your application is executing. In some circumstances it packs your declared elements as closely together as possible; in other cases it aligns their memory addresses to natural hardware boundaries. Also, storage assignment is different on a 64-bit platform than it is on a 32-bit platform.

The same considerations apply to each member of a composite data type such as a structure or an array. Furthermore, some composite types have additional memory requirements. For example, an array uses extra memory for the array itself and also for each dimension. On a 32-bit platform, this overhead is currently 12 bytes plus 8 bytes for each dimension. On a 64-bit platform the requirement is doubled. You cannot rely on simply adding together the nominal storage allocations of the components.

An **Object** referring to any elementary or composite data type uses 4 bytes in addition to the data contained in the data type.

See Also

Boolean Data Type | Byte Data Type | Char Data Type | Date Data Type | Decimal Data Type | Double Data Type | Integer Data Type | Long Data Type | Object Data Type | Short Data Type | Single Data Type | String Data Type | User-Defined Data Type | Type Conversion Functions | Efficient Use of Data Types | Int, Fix Functions | StrConv Function

Boolean Data Type

Boolean variables are stored as 16-bit (2-byte) numbers, but they can only be **True** or **False**. Use the keywords **True** and **False** to assign one of the two states to **Boolean** variables.

When numeric data types are converted to **Boolean** values, 0 becomes **False** and all other values become **True**. When **Boolean** values are converted to numeric types, **False** becomes 0 and **True** becomes -1.

> **Note** The **ToInt32** method of the **Convert** class in the **System** namespace converts **True** to +1. If you need to convert a **Boolean** value to a numeric data type, take care which conversion method you use.
>
> **Caution** You should never write code that relies on equivalent numeric values for **True** and **False**. Whenever possible, you should restrict usage of **Boolean** variables to the logical values for which they are designed. If it is necessary to mix **Boolean** and numeric values, be sure to use the appropriate conversion keywords.

The equivalent .NET data type is **System.Boolean**.

See Also

Data Type Summary | Boolean Structure | Integer Data Type | Type Conversion Functions | Conversion Summary | Convert.ToInt32 Method (Boolean) | Efficient Use of Data Types

Byte Data Type

Byte variables are stored as unsigned 8-bit (1-byte) numbers ranging in value from 0 through 255.

The **Byte** data type is used for containing binary data.

> **Note** The **Byte** data type can be converted to the **Short**, **Integer**, **Long**, **Single**, **Double**, or **Decimal** data type without encountering a **System.OverflowException** error.

The equivalent .NET data type is **System.Byte**.

See Also

Data Type Summary | Byte Structure | Integer Data Type | Short Data Type | Type Conversion Functions | Conversion Summary | Efficient Use of Data Types

Char Data Type

Char variables are stored as unsigned 16-bit (2-byte) numbers ranging in value from 0 through 65535. Each number represents a single Unicode character. Direct conversions between the **Char** data type and the numeric types are not possible, but you can use the **AscW** and **ChrW** functions for this purpose.

Appending the literal type character **C** to a single-character string literal forces it to the **Char** data type. This is required if the type checking switch (**Option Strict**) is on, as the following example shows:

```
Option Strict On
' ...
Dim CharVar As Char
CharVar = "Z"    ' Cannot convert String to Char with Option Strict On.
CharVar = "Z"C   ' Successfully assigns single character to CharVar.
```

The equivalent .NET data type is **System.Char**.

Data Type Summary | Char Structure | Integer Data Type | Type Conversion Functions | Conversion Summary | Implicit and Explicit Conversions | Efficient Use of Data Types | Asc, AscW Functions | Chr, ChrW Functions

Date Data Type

Date variables are stored as IEEE 64-bit (8-byte) integers that represent dates ranging from January 1 of the year 1 through December 31 of the year 9999, and times from 0:00:00 (midnight) through 11:59:59 PM.

Date values must be enclosed within number signs (**#**) and be in the format M/d/yyyy, for example `#5/31/1993#`. If you convert a **Date** value to the **String** type, the date is rendered according to the short date format recognized by your computer, and the time is rendered according to the time format (either 12-hour or 24-hour) in effect on your computer.

The equivalent .NET data type is **System.DateTime**.

See Also

Data Type Summary | DateTime Structure | Double Data Type | Type Conversion Functions | Conversion Summary | Data Type Changes in Visual Basic | Efficient Use of Data Types

Decimal Data Type

Decimal variables are stored as signed 128-bit (16-byte) integers scaled by a variable power of 10. The scaling factor specifies the number of digits to the right of the decimal point; it ranges from 0 through 28. With a scale of 0 (no decimal places), the largest possible value is +/-79,228,162,514,264,337,593,543,950,335. With 28 decimal places, the largest value is +/-7.9228162514264337593543950335, and the smallest nonzero value is +/-0.0000000000000000000000000001 (+/-1E-28).

Appending the literal type character **D** to a literal forces it to the **Decimal** data type. Appending the identifier type character **@** to any identifier forces it to **Decimal**. You might need to use the **D** type character to assign a large value to a **Decimal** variable or constant, as the following example shows:

```
Dim BigDec1 As Decimal = 9223372036854775807   ' No overflow.
Dim BigDec2 As Decimal = 9223372036854775808   ' Overflow.
Dim BigDec3 As Decimal = 9223372036854775808D  ' No overflow.
```

This is because without a literal type character the literal is taken as **Long**, and the value to be assigned to `BigDec2` is too large for the **Long** type.

The equivalent .NET data type is **System.Decimal**.

See Also

Data Type Summary | Decimal Structure | Type Conversion Functions | Conversion Summary | Efficient Use of Data Types

Double Data Type

Double variables are stored as signed IEEE 64-bit (8-byte) double-precision floating-point numbers ranging in value from -1.79769313486231570E+308 through -4.94065645841246544E-324 for negative values and from 4.94065645841246544E-324 through 1.79769313486231570E+308 for positive values.

> **Note** The **Double** data type can be converted to the **Decimal** data type without encountering a **System.OverflowException** error.

Appending the literal type character **R** to a literal forces it to the **Double** data type. Appending the identifier type character **#** to any identifier forces it to **Double**.

The equivalent .NET data type is **System.Double**.

See Also

Data Type Summary | Double Structure | Single Data Type | Type Conversion Functions | Conversion Summary | Efficient Use of Data Types

Integer Data Type

Integer variables are stored as signed 32-bit (4-byte) integers ranging in value from -2,147,483,648 through 2,147,483,647.

The **Integer** data type provides optimal performance on a 32-bit processor, as the smaller integral types are slower to load and store from and to memory.

You can convert the **Integer** data type to **Long**, **Single**, **Double**, or **Decimal** without encountering a **System.OverflowException** error.

> **Caution** If you are interfacing with components written in Visual Basic version 6.0, for example Automation or COM objects, keep in mind that **Integer** has a different data width (16 bits) in Visual Basic 6.0. If you are passing a 16-bit argument to such a component, declare it as **Short** instead of **Integer** in Visual Basic .NET.

Appending the literal type character **I** to a literal forces it to the **Integer** data type. Appending the identifier type character **%** to any identifier forces it to **Integer**.

The equivalent .NET data type is **System.Int32**.

See Also

Data Type Summary | Int32 Structure | Long Data Type | Short Data Type | Type Conversion Functions | Conversion Summary | Integer Data Type Changes in Visual Basic | Efficient Use of Data Types

Long Data Type

Long variables are stored as signed 64-bit (8-byte) integers ranging in value from -9,223,372,036,854,775,808 through 9,223,372,036,854,775,807.

You can convert the **Long** data type to **Single**, **Double**, or **Decimal** without encountering a **System.OverflowException** error.

> **Caution** If you are interfacing with components written in Visual Basic version 6.0, for example Automation or COM objects, keep in mind that **Long** has a different data width (32 bits) in Visual Basic 6.0. If you are passing a 32-bit argument to such a component, declare it as **Integer** instead of **Long** in Visual Basic .NET.
>
> Furthermore, Automation does not support 64-bit integers on certain platforms, including Windows 2000 and Windows 98. You cannot pass a Visual Basic .NET **Long** argument to an Automation component on such platforms.

Appending the literal type character **L** to a literal forces it to the **Long** data type. Appending the identifier type character **&** to any identifier forces it to **Long**.

The equivalent .NET data type is **System.Int64**.

See Also

Data Type Summary | Int64 Structure | Integer Data Type | Short Data Type | Type Conversion Functions | Conversion Summary | Integer Data Type Changes in Visual Basic | Efficient Use of Data Types

Object Data Type

Object variables are stored as 32-bit (4-byte) addresses that refer to objects. You can assign any reference type (string, array, class, or interface) to a variable declared as an **Object**.

An **Object** variable can also refer to data of any value type (numeric, **Boolean**, **Char**, **Date**, structure, or enumeration).

> **Note** Although a variable declared with **Object** type is flexible enough to contain a reference to any object, the invocation of a method of an instance using an **Object** variable is always late (run-time) binding. To force early (compile-time) binding, assign the object reference to a variable declared with a specific class name or cast to the specific data type.

The equivalent .NET data type is **System.Object**.

See Also

Data Type Summary | Object Class | Type Conversion Functions | Conversion Summary | Efficient Use of Data Types

Short Data Type

Short variables are stored as signed 16-bit (2-byte) integers ranging in value from -32,768 through 32,767.

> **Note** The **Short** data type can be converted to the **Integer**, **Long**, **Single**, **Double**, or **Decimal** data type without encountering a **System.OverflowException** error.

Appending the literal type character **S** to a literal forces it to the **Short** data type.

The equivalent .NET data type is **System.Int16**.

See Also

Data Type Summary | Int16 Structure | Type Conversion Functions | Conversion Summary | Byte Data Type | Integer Data Type | Long Data Type | Integer Data Type Changes in Visual Basic | Efficient Use of Data Types

Single Data Type

Single variables are stored as signed IEEE 32-bit (4-byte) single-precision floating-point numbers ranging in value from -3.4028235E+38 through -1.401298E-45 for negative values and from 1.401298E-45 through 3.4028235E+38 for positive values. Single-precision numbers store an approximation of a real number.

> **Note** The **Single** data type can be converted to the **Double** or **Decimal** data type without encountering a **System.OverflowException** error.

Appending the literal type character **F** to a literal forces it to the **Single** data type. Appending the identifier type character **!** to any identifier forces it to **Single**.

The equivalent .NET data type is **System.Single**.

See Also

Data Type Summary | Single Structure | Double Data Type | Type Conversion Functions | Conversion Summary | Efficient Use of Data Types

String Data Type

String variables are stored as sequences of unsigned 16-bit (2-byte) numbers ranging in value from 0 through 65535. Each number represents a single Unicode character. A string can contain up to approximately 2 billion (2 ^ 31) Unicode characters.

The first 128 code points (0–127) of Unicode correspond to the letters and symbols on a standard U.S. keyboard. These first 128 code points are the same as those defined by the ASCII character set. The second 128 code points (128–255) represent special characters, such as Latin-based alphabet letters, accents, currency symbols, and fractions. The remaining code points are used for a wide variety of symbols, including worldwide textual characters, diacritics, and mathematical and technical symbols.

Appending the identifier type character **$** to any identifier forces it to the **String** data type.

The equivalent .NET data type is **System.String**.

See Also

Data Type Summary | String Class | Type Conversion Functions | Conversion Summary | Efficient Use of Data Types

User-Defined Data Type

The user-defined type (UDT) supported by previous versions of Visual Basic is generalized to a *structure* in Visual Basic .NET. A structure is a concatenation of one or more *members* of various data types. The structure is treated as a single unit, although its members can also be accessed individually.

A structure declaration starts with the **Structure** statement and ends with the **End Structure** statement. The **Structure** statement supplies the name of the structure, which is also the identifier of the data type being defined by the structure. Other parts of the code can use this identifier to declare the data type of variables, arguments, and function return values.

The following paradigm shows the declaration of a structure.

```
[Public | Protected | Friend | Protected Friend | Private] Structure structname
   {Dim | Public | Friend | Private} member1 As datatype1
   ...
   {Dim | Public | Friend | Private} memberN As datatypeN
End Structure
```

The declarations between the **Structure** and **End Structure** statements define the members of the structure. Every member must be declared using a **Dim** statement or a statement that specifies access, such as **Public**, **Private**, or **Friend**. If a **Dim** statement is used, the access defaults to public.

> **Note** As with all composite data types, you cannot safely calculate the total memory consumption of a structure by adding together the nominal storage allocations of its members. Furthermore, you cannot safely assume that the order of storage in memory is the same as your order of declaration.

All structures inherit from the .NET class **System.ValueType**.

Directives

In This Section

#Const Directive

#ExternalSource Directive

#If...Then...#Else Directives

#Region Directive

Related Sections

Visual Basic Language and Run-Time Reference

Visual Basic Language

#Const Directive

Defines conditional compiler constants for Visual Basic.

```
#Const constname = expression
```

Parts

constname
Required. **String**. Name of the constant being defined.

expression
Required. Literal, other conditional compiler constant, or any combination that includes any or all arithmetic or logical operators except **Is**.

Remarks

Conditional compiler constants are always private to the file in which they appear. You cannot create public compiler constants using the **#Const** directive; you can create them only in the user interface.

You can use only conditional compiler constants and literals in *expression*. Using a standard constant defined with **#Const** causes an error. Conversely, you can use constants defined with the **#Const** keyword only for conditional compilation. Constants also can be undefined, in which case they have a value of **Nothing**.

Example

This example uses the **#Const** directive.

```
#Const MyLocation = "USA"
#Const Version = "8.0.0012"
#Const CustomerNumber = 36
```

See Also

#If...Then...#Else Directives | Const Statement | Conditional Compilation Overview | Declaring Conditional Compilation Constants | If...Then...Else Statements (Conceptual)

#ExternalSource Directive

Indicates a mapping between specific lines of source code and text external to the source.

```
# ExternalSource( StringLiteral , IntLiteral )
   [ LogicalLine+ ]
# End ExternalSource
```

Parts

StringLiteral
The path to the external source.
IntLiteral
The line number of the first line of the external source.
LogicalLine
The line where the error occurs in the external source.
 # End ExternalSource
Terminates the **#ExternalSource** block.

Remarks

This directive is used only by the compiler and the debugger.

A source file may include external source directives, which indicate a mapping between specific lines of code in the source file and text external to the source, such as an .aspx file. If errors are encountered in the designated source code during compilation, they are identified as coming from the external source.

External source directives have no effect on compilation and may not be nested. They are intended for internal use by the application only.

See Also

Conditional Compilation

#If...Then...#Else Directives

Conditionally compiles selected blocks of Visual Basic code.

```
#If expression Then
   statements
[ #ElseIf expression Then
   [ statements ]
...
#ElseIf expression Then
   [ statements ] ]
[ #Else
   [ statements ] ]
#End If
```

Parts

expression
Required for **If** and **ElseIf** statements, optional elsewhere. Any expression, consisting exclusively of one or more conditional compiler constants, literals, and operators, that evaluates to **True** or **False**. Three conditional compilation constants are provided: **Config**, **Debug**, and **Trace**. **Debug** and **Trace** are **Boolean** datatypes and can be set in the Project Properties dialogue. When **Debug** is defined, Debug class methods generate output to the **Output** window. When it is not defined, Debug class methods are not compiled and no Debug output is generated. Similarly, when **Trace** is defined, Trace class methods generate output to the **Output** window. When it is not defined, Trace class methods are not compiled and no Trace output is generated. **Config** is a string datatype, which corresponds to the current setting in the Configuration Manager.

statements
Required for **If** statement block, optional elsewhere. Visual Basic program lines or compiler directives that are compiled if the associated expression evaluates to **True**.

#End If
Terminates the #**If** statement block.

Remarks

On the surface, the behavior of the **#If...Then...#Else** directives appears the same as that of the **If...Then...Else** statements. However, the **#If...Then...#Else** directives evaluate what is compiled by the compiler, whereas the **If...Then...Else** statements evaluate conditions at run time.

Conditional compilation is typically used to compile the same program for different platforms. It is also used to prevent debugging code from appearing in an executable file. Code excluded during conditional compilation is completely omitted from the final executable file, so it has no effect on size or performance.

Regardless of the outcome of any evaluation, all expressions are evaluated using **Option Compare Text**. The **Option Compare** statement does not affect expressions in **#If** and **#ElseIf** statements.

> **Note** No single-line form of the **#If**, **#Else**, **#ElseIf**, and **#End If** directives exists; that is, no other code can appear on the same line as any of the directives.

Example

This example uses the **#If...Then...#Else** construct to determine whether to compile certain statements.

```
#Const CustomerNumber = 36
#If CustomerNumber = 35 Then
    ' Insert code to be compiled for customer # 35.
#ElseIf CustomerNumber = 36 Then
    ' Insert code to be compiled for customer # 36.
#Else
    ' Insert code to be compiled for all other customers.
#End If
```

See Also

#Const Directive | If...Then...Else Statements (Language Reference) | Conditional Compilation Overview | If...Then...Else Statements (Conceptual)

#Region Directive

Collapses and hides sections of code in Visual Basic .NET files.

```
#Region "identifier_string"
#End Region
```

Parts

identifier_string
Required. String that acts as the title of a region when it is collapsed. Regions are collapsed by default.

#End Region
Terminates the #**Region** block.

Remarks

The **#Region** directive lets you specify a block of code that you can expand or collapse when using the outlining feature of the Visual Studio Code Editor. **#Region** statements support block semantics (such as **#If...#End If**), meaning that the start and end must be in the same code block.

Example

This example uses the **#Region** directive.

```
#Region "MathFunctions"
' Insert code for the Math functions here.
#End Region
```

Math Functions

The math functions in Visual Basic 6 have been replaced by equivalent methods in the **System.Math** class of the .NET Framework.

Remarks

The .NET Framework math methods are functionally identical to their Visual Basic 6 counterparts, although some have slightly different names. For example, the .NET Framework equivalent of the Visual Basic 6 Atn function is **Atan**. The following table lists the Visual Basic 6 math function names and the equivalent .NET Framework methods.

Visual Basic 6 function	Visual Basic .NET method	Description
Abs	Math.Abs Method	Returns the absolute value of a specified number.
Atn	Math.Atan Method	Returns a **Double** value containing the angle whose tangent is the specified number.
Cos	Math.Cos Method	Returns a **Double** value containing the cosine of the specified angle.
Exp	Math.Exp Method	Returns a **Double** value containing e (the base of natural logarithms) raised to the specified power.
Log	Math.Log Method	Returns a **Double** value containing the logarithm of a specified number. This method is overloaded and can return either the natural (base e) logarithm of a specified number or the logarithm of a specified number in a specified base.
Round	Math.Round Method	Returns a **Double** value containing the number nearest the specified value. Additional round functions are available as methods of the intrinsic types such as Decimal.Round Method.
Sgn	Math.Sign Method	Returns an **Integer** value indicating the sign of a number.
Sin	Math.Sin Method	Returns a **Double** value specifying the sine of an angle.
Sqr	Math.Sqrt Method	Returns a **Double** value specifying the square root of a number.
Tan	Math.Tan Method	Returns a **Double** value containing the tangent of an angle.

In addition, the .NET Framework math class provides constants and other static methods for trigonometric, logarithmic, and other common mathematical functions. All of these can be used in a Visual Basic program.

To use these functions without qualification, import the **System.Math** namespace into your project by adding the following code to the top of the source code:

```
Imports System.Math
```

Requirements

Class: Math Class

Abs Example

This example uses the **Abs** method of the **Math** class to compute the absolute value of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyNumber As Double
```

```
MyNumber = Abs(50.3)    ' Returns 50.3.
MyNumber = Abs(-50.3)   ' Returns 50.3.
```

Atan Example

This example uses the **Atan** method of the **Math** class to calculate the value of pi.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim pi As Double
pi = 4 * Atan(1)   ' Calculate the value of pi.
```

Cos Example

This example uses the **Cos** method of the **Math** class to return the cosine of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MySecant As Double
MyAngle = 1.3   ' Define angle in radians.
MySecant = 1 / Cos(MyAngle)   ' Calculate secant.
```

Exp Example

This example uses the **Exp** method of the **Math** class to return *e* raised to a power.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyHSin As Double
' Define angle in radians.
MyAngle = 1.3
' Calculate hyperbolic sine.
MyHSin = (Exp(MyAngle) - Exp(-1 * MyAngle)) / 2
```

Log Example

This example uses the **Log** method of the **Math** class to return the natural logarithm of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyLog As Double
' Define angle in radians.
MyAngle = 1.3
' Calculate inverse hyperbolic sine.
MyLog = Log(MyAngle + Sqrt(MyAngle * MyAngle + 1))
```

Round Example

This example uses the **Round** method of the **Math** class to round a number to the nearest integer.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyVar1 As Double = 2.8
Dim MyVar2 As Double
MyVar2 =Round(MyVar1)   ' Returns 3.
```

Sign Example

This example uses the **Sign** method of the **Math** class to determine the sign of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyVar1, MyVar2, MyVar3 As Double
Dim MySign As Integer
MyVar1 = 12
MyVar2 = -2.4
MyVar3 = 0
MySign = Sign(MyVar1)   ' Returns 1.
MySign = Sign(MyVar2)   ' Returns -1.
MySign = Sign(MyVar3)   ' Returns 0.
```

Sin Example

This example uses the **Sin** method of the **Math** class to return the sine of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyCosecant As Double
MyAngle = 1.3   ' Define angle in radians.
MyCosecant = 1 / Sin(MyAngle)   ' Calculate cosecant.
```

Sqrt Example

This example uses the **Sqrt** method of the **Math** class to calculate the square root of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MySqr As Double
MySqr = Sqrt(4)    ' Returns 2.
MySqr = Sqrt(23)   ' Returns 4.79583152331272.
MySqr = Sqrt(0)    ' Returns 0.
MySqr = Sqrt(-4)   ' Returns NaN (not a number).
```

Tan Example

This example uses the **Tan** method of the **Math** class to return the tangent of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyCotangent As Double
MyAngle = 1.3   ' Define angle in radians.
MyCotangent = 1 / Tan(MyAngle)   ' Calculate cotangent.
```

Requirements

Namespace: System.Math

Assembly: mscorlib (in mscorlib.dll)

See Also

Rnd Function | Randomize Statement | Derived Math Functions | Double.NaN Field

AppActivate Function

Activates an application window.

```
Public Overloads Sub AppActivate( _
   ByVal { Title As String | ProcessID As Integer } _
)
```

Parameters

Title
String expression specifying the title in the title bar of the application window you want to activate. You can use the task ID returned by the **Shell** function.

ProcessID
Integer specifying the Win32 Process ID number assigned to this process.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*ProcessID* is not found .

Remarks

The **AppActivate** function changes the focus to the named application or window, but does not affect whether it is maximized or minimized. Focus moves from the activated application window when the user takes some action to change the focus or close the window. Use the **Shell** function to start an application and set the window style.

You can use **AppActivate** only with processes that own windows. Most console applications do not own windows, which means that they do not appear in the list of processes that **AppActivate** searches. When running from a console application, the system creates a separate process to run the application and returns the output to the console process. Consequently, when the current Process ID is requested, you get the created process's Process ID rather than the console application's Process ID.

At run time the **AppActivate** function activates any running application whose title matches *Title* or whose Process ID matches *ProcessID*. If there is no exact match, it activates any application whose title string begins with *Title*. If there is more than one application named by *Title*, the **AppActivate** function activates one at random.

> **Note** The **AppActivate** function requires UIPermission at the SafeTopLevelWindows level, which may affect its execution in partial trust situations. For more information, see Requesting Permissions and UIPermission Class.

Example

This example illustrates various uses of the **AppActivate** function to activate an application window. If a notepad process is not running, the example throws an exception. The **Shell** procedure assumes the applications are in the paths specified.

```
Dim notepadID As Integer
' Activate a running notepad process.
AppActivate("Untitled - Notepad")
' AppActivate can also use the return value of the Shell function.
' Shell runs a new instance of notepad.
notepadID = Shell("C:\WINNT\NOTEPAD.EXE", AppWinStyle.MinimizedNoFocus)
' Activate the new instance of notepad.
AppActivate(notepadID)
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: Interaction

Assembly: Microsoft.Visual Basic .NET Runtime (in MicrosoftVisualBasic.dll)

See Also

Shell Function | ArgumentException Class

Asc, AscW Functions

Returns an **Integer** value representing the character code corresponding to a character.

```
Public Overloads Function Asc(ByVal String As Char) As Integer
Public Overloads Function AscW(ByVal String As Char) As Integer
```

-or-

```
Public Overloads Function Asc(ByVal String As String) As Integer
Public Overloads Function AscW(ByVal String As String) As Integer
```

Parameter

String
Required. Any valid **Char** or **String** expression. If *String* is a **String** expression, only the first character of the string is used for input. If *String* is **Nothing** or contains no characters, an **ArgumentException** error occurs.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*String* is not specified or is zero length.

Remarks

Asc returns the *code point*, or character code, for the input character. This can be 0 through 255 for single-byte character set (SBCS) values and -32768 through 32767 for double-byte character set (DBCS) values. The returned value depends on the code page for the current thread, which is contained in the **ANSICodePage** property of the **TextInfo** class. **TextInfo.ANSICodePage** can be obtained by specifying **System.Globalization.CultureInfo.CurrentCulture.TextInfo.ANSICodePage**.

AscW returns the Unicode code point for the input character. This can be 0 through 65535. The returned value is independent of the culture and code page settings for the current thread.

> **Note** The **AscB** function of earlier versions of Visual Basic returns a code for a byte, rather than a character. It is used primarily for converting strings in double-byte character set (DBCS) applications. All Visual Basic .NET strings are in Unicode, and **AscB** is no longer supported.

Example

This example uses the **Asc** function to return **Integer** character codes corresponding to the first letter in each string.

```
Dim MyInt As Integer
MyInt = Asc("A")   ' MyInt is set to 65.
MyInt = Asc("a")   ' MyInt is set to 97.
MyInt = Asc("Apple")   ' MyInt is set to 65.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Asc, AscW Functions

Returns an **Integer** value representing the character code corresponding to a character.

```
Public Overloads Function Asc(ByVal String As Char) As Integer
Public Overloads Function AscW(ByVal String As Char) As Integer
```

-or-

```
Public Overloads Function Asc(ByVal String As String) As Integer
Public Overloads Function AscW(ByVal String As String) As Integer
```

Parameter

String
Required. Any valid **Char** or **String** expression. If *String* is a **String** expression, only the first character of the string is used for input. If *String* is **Nothing** or contains no characters, an **ArgumentException** error occurs.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*String* is not specified or is zero length.

Remarks

Asc returns the *code point*, or character code, for the input character. This can be 0 through 255 for single-byte character set (SBCS) values and -32768 through 32767 for double-byte character set (DBCS) values. The returned value depends on the code page for the current thread, which is contained in the **ANSICodePage** property of the **TextInfo** class. **TextInfo.ANSICodePage** can be obtained by specifying **System.Globalization.CultureInfo.CurrentCulture.TextInfo.ANSICodePage**.

AscW returns the Unicode code point for the input character. This can be 0 through 65535. The returned value is independent of the culture and code page settings for the current thread.

> **Note** The **AscB** function of earlier versions of Visual Basic returns a code for a byte, rather than a character. It is used primarily for converting strings in double-byte character set (DBCS) applications. All Visual Basic .NET strings are in Unicode, and **AscB** is no longer supported.

Example

This example uses the **Asc** function to return **Integer** character codes corresponding to the first letter in each string.

```
Dim MyInt As Integer
MyInt = Asc("A")   ' MyInt is set to 65.
MyInt = Asc("a")   ' MyInt is set to 97.
MyInt = Asc("Apple")   ' MyInt is set to 65.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Math Functions

The math functions in Visual Basic 6 have been replaced by equivalent methods in the **System.Math** class of the .NET Framework.

Remarks

The .NET Framework math methods are functionally identical to their Visual Basic 6 counterparts, although some have slightly different names. For example, the .NET Framework equivalent of the Visual Basic 6 Atn function is **Atan**. The following table lists the Visual Basic 6 math function names and the equivalent .NET Framework methods.

Visual Basic 6 function	Visual Basic .NET method	Description
Abs	Math.Abs Method	Returns the absolute value of a specified number.
Atn	Math.Atan Method	Returns a **Double** value containing the angle whose tangent is the specified number.
Cos	Math.Cos Method	Returns a **Double** value containing the cosine of the specified angle.
Exp	Math.Exp Method	Returns a **Double** value containing e (the base of natural logarithms) raised to the specified power.
Log	Math.Log Method	Returns a **Double** value containing the logarithm of a specified number. This method is overloaded and can return either the natural (base e) logarithm of a specified number or the logarithm of a specified number in a specified base.
Round	Math.Round Method	Returns a **Double** value containing the number nearest the specified value. Additional round functions are available as methods of the intrinsic types such as Decimal.Round Method.
Sgn	Math.Sign Method	Returns an **Integer** value indicating the sign of a number.
Sin	Math.Sin Method	Returns a **Double** value specifying the sine of an angle.
Sqr	Math.Sqrt Method	Returns a **Double** value specifying the square root of a number.
Tan	Math.Tan Method	Returns a **Double** value containing the tangent of an angle.

In addition, the .NET Framework math class provides constants and other static methods for trigonometric, logarithmic, and other common mathematical functions. All of these can be used in a Visual Basic program.

To use these functions without qualification, import the **System.Math** namespace into your project by adding the following code to the top of the source code:

```
Imports System.Math
```

Requirements

Class: Math Class

Abs Example

This example uses the **Abs** method of the **Math** class to compute the absolute value of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyNumber As Double
```

```
MyNumber = Abs(50.3)    ' Returns 50.3.
MyNumber = Abs(-50.3)   ' Returns 50.3.
```

Atan Example

This example uses the **Atan** method of the **Math** class to calculate the value of pi.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim pi As Double
pi = 4 * Atan(1)   ' Calculate the value of pi.
```

Cos Example

This example uses the **Cos** method of the **Math** class to return the cosine of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MySecant As Double
MyAngle = 1.3   ' Define angle in radians.
MySecant = 1 / Cos(MyAngle)   ' Calculate secant.
```

Exp Example

This example uses the **Exp** method of the **Math** class to return *e* raised to a power.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyHSin As Double
' Define angle in radians.
MyAngle = 1.3
' Calculate hyperbolic sine.
MyHSin = (Exp(MyAngle) - Exp(-1 * MyAngle)) / 2
```

Log Example

This example uses the **Log** method of the **Math** class to return the natural logarithm of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyLog As Double
' Define angle in radians.
MyAngle = 1.3
' Calculate inverse hyperbolic sine.
MyLog = Log(MyAngle + Sqrt(MyAngle * MyAngle + 1))
```

Round Example

This example uses the **Round** method of the **Math** class to round a number to the nearest integer.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyVar1 As Double = 2.8
Dim MyVar2 As Double
MyVar2 =Round(MyVar1)   ' Returns 3.
```

Sign Example

This example uses the **Sign** method of the **Math** class to determine the sign of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyVar1, MyVar2, MyVar3 As Double
Dim MySign As Integer
MyVar1 = 12
MyVar2 = -2.4
MyVar3 = 0
MySign = Sign(MyVar1)   ' Returns 1.
MySign = Sign(MyVar2)   ' Returns -1.
MySign = Sign(MyVar3)   ' Returns 0.
```

Sin Example

This example uses the **Sin** method of the **Math** class to return the sine of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyCosecant As Double
MyAngle = 1.3   ' Define angle in radians.
MyCosecant = 1 / Sin(MyAngle)   ' Calculate cosecant.
```

Sqrt Example

This example uses the **Sqrt** method of the **Math** class to calculate the square root of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MySqr As Double
MySqr = Sqrt(4)    ' Returns 2.
MySqr = Sqrt(23)   ' Returns 4.79583152331272.
MySqr = Sqrt(0)    ' Returns 0.
MySqr = Sqrt(-4)   ' Returns NaN (not a number).
```

Tan Example

This example uses the **Tan** method of the **Math** class to return the tangent of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyCotangent As Double
MyAngle = 1.3   ' Define angle in radians.
MyCotangent = 1 / Tan(MyAngle)   ' Calculate cotangent.
```

Requirements

Namespace: System.Math

Assembly: mscorlib (in mscorlib.dll)

Beep Function

Sounds a tone through the computer's speaker.

```
Public Sub Beep()
```

Remarks

The pitch and duration of the beep depend on your hardware and system software, and therefore vary among computers.

> **Note** The **Beep** function requires UIPermission at the SafeTopLevelWindows level, which may affect its execution in partial trust situations. For more information, see Requesting Permissions and UIPermission Class.

Example

This example uses the **Beep** function to sound a long, uninterrupted tone through the computer's speaker.

```
Dim I As Integer
For I = 1 To 100   ' Loop 100 times.
   Beep   ' Sound a tone.
Next I
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Interaction

Assembly: Microsoft.Visual Basic .NET Runtime (in MicrosoftVisualBasic.dll)

Visual Basic Run-Time Library Members

CallByName Function

Executes a method on an object, or sets or returns a property on an object.

```
Public Function CallByName( _
   ByVal Object As System.Object, _
   ByVal ProcName As String, _
   ByVal UseCallType As CallType, _
   ByVal ParamArrayArgs() As Object _
) As Object
```

Parameters

Object
Required. **Object**. A pointer to the object exposing the property or method.
ProcName
Required. **String**. A string expression containing the name of the property or method on the object.
UseCallType
Required. An enumeration member of type **Microsoft.VisualBasic.CallType** representing the type of procedure being called. The value of **CallType** can be **Method**, **Get**, or **Set**.
ParamArrayArgs()
Optional. **ParamArray**. A parameter array containing the arguments to be passed to the property or method being called.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	Invalid *UseCallType* value; must be **Method**, **Get**, or **Set.**

Remarks

The **CallByName** function is used at runtime to get a property, set a property, or invoke a method.

Example

In the following example, the first line uses **CallByName** to set the **Text** property of a text box, the second line retrieves the value of the **Text** property, and the third line invokes the **Move** method to move the text box.

```
Imports Microsoft.VisualBasic.CallType
' Imports statements must be at the top of a module.
...
Sub TestCallByName1()
'  Set a property.
   CallByName(TextBox1, "Text", CallType.Set, "New Text")
'  Retrieve the value of a property.
   MsgBox(CallByName(TextBox1, "Text", CallType.Get))
'  Call a method.
   CallByName(TextBox1, "Hide", CallType.Method)
End Sub
```

The next example uses the **CallByName** function to invoke the **Add** and **Item** methods of a collection object.

```
Public Sub TestCallByName2()
   Dim col As New Collection()
'  Store the string "Item One" in a collection by
'  calling the Add method.
   CallByName(col, "Add", CallType.Method, "Item One")
'  Retrieve the first entry from the collection using the
'  Item property and display it using MsgBox().
   MsgBox(CallByName(col, "Item", CallType.Get, 1))
End Sub
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: Interaction

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Type Conversion Functions

These functions are compiled inline, meaning the conversion code is part of the code that evaluates the expression. Execution is faster because there is no call to a procedure to accomplish the conversion. Each function coerces an expression to a specific data type.

```
CBool(expression)
CByte(expression)
CChar(expression)
CDate(expression)
CDbl(expression)
CDec(expression)
CInt(expression)
CLng(expression)
CObj(expression)
CShort(expression)
CSng(expression)
CStr(expression)
```

Part

expression
Required. Any **String** expression or numeric expression.

Return Types

The function name determines the return type, as shown in the following table:

Function name	Return type	Range for *expression* argument
CBool	**Boolean**	Any valid **String** or numeric expression.
CByte	**Byte**	0 through 255; fractions are rounded.
CChar	**Char**	Any valid **String** expression; value can be 0 through 65535.
CDate	**Date**	Any valid representation of a date and time.
CDbl	**Double**	-1.79769313486231E+308 through -4.94065645841247E-324 for negative values; 4.94065645841247E-324 through 1.79769313486231E+308 for positive values.
CDec	**Decimal**	+/-79,228,162,514,264,337,593,543,950,335 for zero-scaled numbers, that is, numbers with no decimal places. For numbers with 28 decimal places, the range is +/-7.9228162514264337593543950335. The smallest possible non-zero number is 0.0000000000000000000000000001.
CInt	**Integer**	-2,147,483,648 through 2,147,483,647; fractions are rounded.
CLng	**Long**	-9,223,372,036,854,775,808 through 9,223,372,036,854,775,807; fractions are rounded.
CObj	**Object**	Any valid expression.
CShort	**Short**	-32,768 through 32,767; fractions are rounded.
CSng	**Single**	-3.402823E+38 through -1.401298E-45 for negative values; 1.401298E-45 through 3.402823E+38 for positive values.
CStr	**String**	Returns for **CStr** depend on the *expression* argument. See Returns for CStr.

Remarks

If the *expression* passed to the function is outside the range of the data type to which it is being converted, an error occurs.

In general, you can use the data type conversion functions to force the result of some operation to a particular data type rather than the default data type. For example, use **CDec** to force decimal arithmetic in cases where single-precision, double-precision, or integer arithmetic normally would occur.

When the fractional part is exactly 0.5, **CInt** and **CLng** always round it to the nearest even number. For example, 0.5 rounds to 0

and 1.5 rounds to 2. **CInt** and **CLng** differ from the **Fix** and **Int** functions, which truncate, rather than round, the fractional part of a number. Also, **Fix** and **Int** always return a value of the same type as is passed in.

Use the **IsDate** function to determine if a value can be converted to a date and time. **CDate** recognizes date literals and time literals as well as numbers that fall within the range of acceptable dates.

CDate recognizes date formats according to the locale setting of your system. You must provide the day, month, and year in the correct order for your locale, or the date may not be interpreted correctly. A long date format is not recognized if it contains a day-of-the-week string, such as "Wednesday".

The **Date** data type always contains both date and time information. For purposes of type conversion, Visual Basic .NET considers 1/1/1 (January 1 of the year 1) to be a neutral value for the date, and 00:00:00 (midnight) to be a neutral value for the time. If you convert a **Date** value to a string, **CStr** does not include neutral values in the resulting string. For example, if you convert `#January 1, 0001 9:30:00#` to a string, the result is "9:30:00 AM"; the date information is suppressed. However, the date information is still present in the original **Date** value and can be recovered with functions such as **DatePart**.

The **CType** function takes a second argument, *typename*, and coerces *expression* to *typename*, where *typename* can be any data type, structure, class, or interface. For more information, see CType Function.

CBool Example

This example uses the **CBool** function to convert expressions to **Boolean** values. If an expression evaluates to a nonzero value, **CBool** returns **True**; otherwise, it returns **False**.

```
Dim A, B, C As Integer
Dim Check As Boolean
A = 5
B = 5
Check = CBool(A = B)   ' Check is set to True.
' ...
C = 0
Check = CBool(C)   ' Check is set to False.
```

CByte Example

This example uses the **CByte** function to convert an expression to a **Byte**.

```
Dim MyDouble As Double
Dim MyByte As Byte
MyDouble = 125.5678
MyByte = CByte(MyDouble)   ' MyByte is set to 126.
```

CChar Example

This example uses the **CChar** function to convert a the first character of a **String** expression to a **Char** type.

```
Dim MyString As String
Dim MyChar As Char
MyString = "BCD"   ' CChar converts only first character of string.
MyChar = CChar(MyString)   ' MyChar is set to "B".
```

The input argument to **CChar** must be of data type **String**. You cannot use **CChar** to convert a number to a character, because **CChar** cannot accept a numeric data type. This example obtains a number representing a code point (character code) and converts it to the corresponding character. It uses **InputBox** to obtain the string of digits, **CInt** to convert the string to type **Integer**, and **ChrW** to convert the number to type **Char**.

```
Dim MyDigits As String   ' Input string of digits to be converted.
Dim CodePoint As Integer   ' Number to be represented as a character.
Dim MyChar As Char
MyDigits = InputBox("Enter code point of character:")
CodePoint = CInt(MyDigits)   ' Convert entire string to Integer.
MyChar = ChrW(CodePoint)   ' MyChar is set to Char value of code point.
```

CDate Example

This example uses the **CDate** function to convert strings to **Date** values. In general, hard-coding dates and times as strings (as shown in this example) is not recommended. Use date literals and time literals, such as #Feb 12, 1969# and #4:45:23 PM#, instead.

```
Dim MyDateString, MyTimeString As String
Dim MyDate, MyTime As Date
MyDateString = "February 12, 1969"
MyTimeString = "4:35:47 PM"
' ...
MyDate = CDate(MyDateString)   ' Convert to Date data type.
MyTime = CDate(MyTimeString)   ' Convert to Date data type.
```

CDbl Example

This example uses the **CDbl** function to convert an expression to **Double**.

```
Dim MyDec As Decimal
Dim MyDouble As Double
MyDec = 234.456784D    ' Literal type character D makes MyDec a Decimal.
MyDouble = CDbl(MyDec * 8.2D * 0.01D)   ' Convert result to a Double.
```

CDec Example

This example uses the **CDec** function to convert a numeric value to **Decimal**.

```
Dim MyDouble As Double
Dim MyDecimal As Decimal
MyDouble = 10000000.0587
MyDecimal = CDec(MyDouble)   ' Convert to Decimal.
```

CInt Example

This example uses the **CInt** function to convert a value to **Integer**.

```
Dim MyDouble As Double
Dim MyInt As Integer
MyDouble = 2345.5678
MyInt = CInt(MyDouble)   ' MyInt is set to 2346.
```

CLng Example

This example uses the **CLng** function to convert values to **Long**.

```
Dim MyDbl1, MyDbl2 As Double
Dim MyLong1, MyLong2 As Long
MyDbl1 = 25427.45
MyDbl2 = 25427.55
MyLong1 = CLng(MyDbl1)   ' MyLong1 contains 25427.
MyLong2 = CLng(MyDbl2)   ' MyLong2 contains 25428.
```

CObj Example

This example uses the **CObj** function to convert a numeric value to **Object**. The **Object** variable itself contains only a four-byte pointer, which points to the **Double** value assigned to it.

```
Dim MyDouble As Double
Dim MyObject As Object
```

```
MyDouble = 2.7182818284
MyObject = CObj(MyDouble)   ' Double value is pointed to by MyObject.
```

CShort Example

This example uses the **CShort** function to convert a numeric value to **Short**.

```
Dim MyByte as Byte
Dim MyShort as Short
MyByte = 100
MyShort = CShort(MyByte)   ' Convert to Short.
```

CSng Example

This example uses the **CSng** function to convert values to **Single**.

```
Dim MyDouble1, MyDouble2 As Double
Dim MySingle1, MySingle2 As Single
MyDouble1 = 75.3421105
MyDouble2 = 75.3421567
MySingle1 = CSng(MyDouble1)   ' MySingle1 is set to 75.34211.
MySingle2 = CSng(MyDouble2)   ' MySingle2 is set to 75.34216.
```

CStr Example

This example uses the **CStr** function to convert a numeric value to **String**.

```
Dim MyDouble As Double
Dim MyString As String
MyDouble = 437.324
MyString = CStr(MyDouble)   ' MyString is set to "437.324".
```

This example uses the **CStr** function to convert **Date** values to **String** values.

```
Dim MyDate As Date
Dim MyString As String
' ...
MyDate = #February 12, 1969 00:00:00#   ' INVALID format.
' Date literals must be in the format #m/d/yyyy# or they are invalid.
' ...
MyDate = #2/12/69 00:00:00#   ' Time is midnight.
' The neutral time value of 00:00:00 is suppressed in the conversion.
MyString = CStr(MyDate)   ' MyString is set to "2/12/1969".
' ...
MyDate = #2/12/69 00:00:01#   ' Time is one second past midnight.
' The time component becomes part of the converted value.
MyString = CStr(MyDate)   ' MyString is set to "2/12/1969 12:00:01 AM".
```

CStr always renders a **Date** value in the standard short format for the current locale, for example, "6/15/2003 4:35:47 PM".

Conversion Functions | CType Function | Asc, AscW Functions | Chr, ChrW Functions | Format Function | Hex Function | Oct Function | Str Function | Val Function | DatePart Function | Returns for CStr | Type Conversions

Type Conversion Functions

These functions are compiled inline, meaning the conversion code is part of the code that evaluates the expression. Execution is faster because there is no call to a procedure to accomplish the conversion. Each function coerces an expression to a specific data type.

```
CBool(expression)
CByte(expression)
CChar(expression)
CDate(expression)
CDbl(expression)
CDec(expression)
CInt(expression)
CLng(expression)
CObj(expression)
CShort(expression)
CSng(expression)
CStr(expression)
```

Part

expression
Required. Any **String** expression or numeric expression.

Return Types

The function name determines the return type, as shown in the following table:

Function name	Return type	Range for *expression* argument
CBool	**Boolean**	Any valid **String** or numeric expression.
CByte	**Byte**	0 through 255; fractions are rounded.
CChar	**Char**	Any valid **String** expression; value can be 0 through 65535.
CDate	**Date**	Any valid representation of a date and time.
CDbl	**Double**	-1.79769313486231E+308 through -4.94065645841247E-324 for negative values; 4.94065645841247E-324 through 1.79769313486231E+308 for positive values.
CDec	**Decimal**	+/-79,228,162,514,264,337,593,543,950,335 for zero-scaled numbers, that is, numbers with no decimal places. For numbers with 28 decimal places, the range is +/-7.9228162514264337593543950335. The smallest possible non-zero number is 0.0000000000000000000000000001.
CInt	**Integer**	-2,147,483,648 through 2,147,483,647; fractions are rounded.
CLng	**Long**	-9,223,372,036,854,775,808 through 9,223,372,036,854,775,807; fractions are rounded.
CObj	**Object**	Any valid expression.
CShort	**Short**	-32,768 through 32,767; fractions are rounded.
CSng	**Single**	-3.402823E+38 through -1.401298E-45 for negative values; 1.401298E-45 through 3.402823E+38 for positive values.
CStr	**String**	Returns for **CStr** depend on the *expression* argument. See Returns for CStr.

Remarks

If the *expression* passed to the function is outside the range of the data type to which it is being converted, an error occurs.

In general, you can use the data type conversion functions to force the result of some operation to a particular data type rather than the default data type. For example, use **CDec** to force decimal arithmetic in cases where single-precision, double-precision, or integer arithmetic normally would occur.

When the fractional part is exactly 0.5, **CInt** and **CLng** always round it to the nearest even number. For example, 0.5 rounds to 0

and 1.5 rounds to 2. **CInt** and **CLng** differ from the **Fix** and **Int** functions, which truncate, rather than round, the fractional part of a number. Also, **Fix** and **Int** always return a value of the same type as is passed in.

Use the **IsDate** function to determine if a value can be converted to a date and time. **CDate** recognizes date literals and time literals as well as numbers that fall within the range of acceptable dates.

CDate recognizes date formats according to the locale setting of your system. You must provide the day, month, and year in the correct order for your locale, or the date may not be interpreted correctly. A long date format is not recognized if it contains a day-of-the-week string, such as "Wednesday".

The **Date** data type always contains both date and time information. For purposes of type conversion, Visual Basic .NET considers 1/1/1 (January 1 of the year 1) to be a neutral value for the date, and 00:00:00 (midnight) to be a neutral value for the time. If you convert a **Date** value to a string, **CStr** does not include neutral values in the resulting string. For example, if you convert `#January 1, 0001 9:30:00#` to a string, the result is "9:30:00 AM"; the date information is suppressed. However, the date information is still present in the original **Date** value and can be recovered with functions such as **DatePart**.

The **CType** function takes a second argument, *typename*, and coerces *expression* to *typename*, where *typename* can be any data type, structure, class, or interface. For more information, see CType Function.

CBool Example

This example uses the **CBool** function to convert expressions to **Boolean** values. If an expression evaluates to a nonzero value, **CBool** returns **True**; otherwise, it returns **False**.

```
Dim A, B, C As Integer
Dim Check As Boolean
A = 5
B = 5
Check = CBool(A = B)   ' Check is set to True.
' ...
C = 0
Check = CBool(C)   ' Check is set to False.
```

CByte Example

This example uses the **CByte** function to convert an expression to a **Byte**.

```
Dim MyDouble As Double
Dim MyByte As Byte
MyDouble = 125.5678
MyByte = CByte(MyDouble)   ' MyByte is set to 126.
```

CChar Example

This example uses the **CChar** function to convert a the first character of a **String** expression to a **Char** type.

```
Dim MyString As String
Dim MyChar As Char
MyString = "BCD"   ' CChar converts only first character of string.
MyChar = CChar(MyString)   ' MyChar is set to "B".
```

The input argument to **CChar** must be of data type **String**. You cannot use **CChar** to convert a number to a character, because **CChar** cannot accept a numeric data type. This example obtains a number representing a code point (character code) and converts it to the corresponding character. It uses **InputBox** to obtain the string of digits, **CInt** to convert the string to type **Integer**, and **ChrW** to convert the number to type **Char**.

```
Dim MyDigits As String   ' Input string of digits to be converted.
Dim CodePoint As Integer   ' Number to be represented as a character.
Dim MyChar As Char
MyDigits = InputBox("Enter code point of character:")
CodePoint = CInt(MyDigits)   ' Convert entire string to Integer.
MyChar = ChrW(CodePoint)   ' MyChar is set to Char value of code point.
```

CDate Example

This example uses the **CDate** function to convert strings to **Date** values. In general, hard-coding dates and times as strings (as shown in this example) is not recommended. Use date literals and time literals, such as #Feb 12, 1969# and #4:45:23 PM#, instead.

```
Dim MyDateString, MyTimeString As String
Dim MyDate, MyTime As Date
MyDateString = "February 12, 1969"
MyTimeString = "4:35:47 PM"
' ...
MyDate = CDate(MyDateString)   ' Convert to Date data type.
MyTime = CDate(MyTimeString)   ' Convert to Date data type.
```

CDbl Example

This example uses the **CDbl** function to convert an expression to **Double**.

```
Dim MyDec As Decimal
Dim MyDouble As Double
MyDec = 234.456784D    ' Literal type character D makes MyDec a Decimal.
MyDouble = CDbl(MyDec * 8.2D * 0.01D)   ' Convert result to a Double.
```

CDec Example

This example uses the **CDec** function to convert a numeric value to **Decimal**.

```
Dim MyDouble As Double
Dim MyDecimal As Decimal
MyDouble = 10000000.0587
MyDecimal = CDec(MyDouble)   ' Convert to Decimal.
```

CInt Example

This example uses the **CInt** function to convert a value to **Integer**.

```
Dim MyDouble As Double
Dim MyInt As Integer
MyDouble = 2345.5678
MyInt = CInt(MyDouble)   ' MyInt is set to 2346.
```

CLng Example

This example uses the **CLng** function to convert values to **Long**.

```
Dim MyDbl1, MyDbl2 As Double
Dim MyLong1, MyLong2 As Long
MyDbl1 = 25427.45
MyDbl2 = 25427.55
MyLong1 = CLng(MyDbl1)   ' MyLong1 contains 25427.
MyLong2 = CLng(MyDbl2)   ' MyLong2 contains 25428.
```

CObj Example

This example uses the **CObj** function to convert a numeric value to **Object**. The **Object** variable itself contains only a four-byte pointer, which points to the **Double** value assigned to it.

```
Dim MyDouble As Double
Dim MyObject As Object
```

```
MyDouble = 2.7182818284
MyObject = CObj(MyDouble)   ' Double value is pointed to by MyObject.
```

CShort Example

This example uses the **CShort** function to convert a numeric value to **Short**.

```
Dim MyByte as Byte
Dim MyShort as Short
MyByte = 100
MyShort = CShort(MyByte)   ' Convert to Short.
```

CSng Example

This example uses the **CSng** function to convert values to **Single**.

```
Dim MyDouble1, MyDouble2 As Double
Dim MySingle1, MySingle2 As Single
MyDouble1 = 75.3421105
MyDouble2 = 75.3421567
MySingle1 = CSng(MyDouble1)   ' MySingle1 is set to 75.34211.
MySingle2 = CSng(MyDouble2)   ' MySingle2 is set to 75.34216.
```

CStr Example

This example uses the **CStr** function to convert a numeric value to **String**.

```
Dim MyDouble As Double
Dim MyString As String
MyDouble = 437.324
MyString = CStr(MyDouble)   ' MyString is set to "437.324".
```

This example uses the **CStr** function to convert **Date** values to **String** values.

```
Dim MyDate As Date
Dim MyString As String
' ...
MyDate = #February 12, 1969 00:00:00#   ' INVALID format.
' Date literals must be in the format #m/d/yyyy# or they are invalid.
' ...
MyDate = #2/12/69 00:00:00#   ' Time is midnight.
' The neutral time value of 00:00:00 is suppressed in the conversion.
MyString = CStr(MyDate)   ' MyString is set to "2/12/1969".
' ...
MyDate = #2/12/69 00:00:01#   ' Time is one second past midnight.
' The time component becomes part of the converted value.
MyString = CStr(MyDate)   ' MyString is set to "2/12/1969 12:00:01 AM".
```

CStr always renders a **Date** value in the standard short format for the current locale, for example, "6/15/2003 4:35:47 PM".

Type Conversion Functions

These functions are compiled inline, meaning the conversion code is part of the code that evaluates the expression. Execution is faster because there is no call to a procedure to accomplish the conversion. Each function coerces an expression to a specific data type.

```
CBool(expression)
CByte(expression)
CChar(expression)
CDate(expression)
CDbl(expression)
CDec(expression)
CInt(expression)
CLng(expression)
CObj(expression)
CShort(expression)
CSng(expression)
CStr(expression)
```

Part

expression
Required. Any **String** expression or numeric expression.

Return Types

The function name determines the return type, as shown in the following table:

Function name	Return type	Range for *expression* argument
CBool	**Boolean**	Any valid **String** or numeric expression.
CByte	**Byte**	0 through 255; fractions are rounded.
CChar	**Char**	Any valid **String** expression; value can be 0 through 65535.
CDate	**Date**	Any valid representation of a date and time.
CDbl	**Double**	-1.79769313486231E+308 through -4.94065645841247E-324 for negative values; 4.94065645841247E-324 through 1.79769313486231E+308 for positive values.
CDec	**Decimal**	+/-79,228,162,514,264,337,593,543,950,335 for zero-scaled numbers, that is, numbers with no decimal places. For numbers with 28 decimal places, the range is +/-7.9228162514264337593543950335. The smallest possible non-zero number is 0.0000000000000000000000000001.
CInt	**Integer**	-2,147,483,648 through 2,147,483,647; fractions are rounded.
CLng	**Long**	-9,223,372,036,854,775,808 through 9,223,372,036,854,775,807; fractions are rounded.
CObj	**Object**	Any valid expression.
CShort	**Short**	-32,768 through 32,767; fractions are rounded.
CSng	**Single**	-3.402823E+38 through -1.401298E-45 for negative values; 1.401298E-45 through 3.402823E+38 for positive values.
CStr	**String**	Returns for **CStr** depend on the *expression* argument. See Returns for CStr.

Remarks

If the *expression* passed to the function is outside the range of the data type to which it is being converted, an error occurs.

In general, you can use the data type conversion functions to force the result of some operation to a particular data type rather than the default data type. For example, use **CDec** to force decimal arithmetic in cases where single-precision, double-precision, or integer arithmetic normally would occur.

When the fractional part is exactly 0.5, **CInt** and **CLng** always round it to the nearest even number. For example, 0.5 rounds to 0

and 1.5 rounds to 2. **CInt** and **CLng** differ from the **Fix** and **Int** functions, which truncate, rather than round, the fractional part of a number. Also, **Fix** and **Int** always return a value of the same type as is passed in.

Use the **IsDate** function to determine if a value can be converted to a date and time. **CDate** recognizes date literals and time literals as well as numbers that fall within the range of acceptable dates.

CDate recognizes date formats according to the locale setting of your system. You must provide the day, month, and year in the correct order for your locale, or the date may not be interpreted correctly. A long date format is not recognized if it contains a day-of-the-week string, such as "Wednesday".

The **Date** data type always contains both date and time information. For purposes of type conversion, Visual Basic .NET considers 1/1/1 (January 1 of the year 1) to be a neutral value for the date, and 00:00:00 (midnight) to be a neutral value for the time. If you convert a **Date** value to a string, **CStr** does not include neutral values in the resulting string. For example, if you convert `#January 1, 0001 9:30:00#` to a string, the result is "9:30:00 AM"; the date information is suppressed. However, the date information is still present in the original **Date** value and can be recovered with functions such as **DatePart**.

The **CType** function takes a second argument, *typename*, and coerces *expression* to *typename*, where *typename* can be any data type, structure, class, or interface. For more information, see CType Function.

CBool Example

This example uses the **CBool** function to convert expressions to **Boolean** values. If an expression evaluates to a nonzero value, **CBool** returns **True**; otherwise, it returns **False**.

```
Dim A, B, C As Integer
Dim Check As Boolean
A = 5
B = 5
Check = CBool(A = B)   ' Check is set to True.
' ...
C = 0
Check = CBool(C)   ' Check is set to False.
```

CByte Example

This example uses the **CByte** function to convert an expression to a **Byte**.

```
Dim MyDouble As Double
Dim MyByte As Byte
MyDouble = 125.5678
MyByte = CByte(MyDouble)   ' MyByte is set to 126.
```

CChar Example

This example uses the **CChar** function to convert a the first character of a **String** expression to a **Char** type.

```
Dim MyString As String
Dim MyChar As Char
MyString = "BCD"   ' CChar converts only first character of string.
MyChar = CChar(MyString)   ' MyChar is set to "B".
```

The input argument to **CChar** must be of data type **String**. You cannot use **CChar** to convert a number to a character, because **CChar** cannot accept a numeric data type. This example obtains a number representing a code point (character code) and converts it to the corresponding character. It uses **InputBox** to obtain the string of digits, **CInt** to convert the string to type **Integer**, and **ChrW** to convert the number to type **Char**.

```
Dim MyDigits As String   ' Input string of digits to be converted.
Dim CodePoint As Integer   ' Number to be represented as a character.
Dim MyChar As Char
MyDigits = InputBox("Enter code point of character:")
CodePoint = CInt(MyDigits)   ' Convert entire string to Integer.
MyChar = ChrW(CodePoint)   ' MyChar is set to Char value of code point.
```

CDate Example

This example uses the **CDate** function to convert strings to **Date** values. In general, hard-coding dates and times as strings (as shown in this example) is not recommended. Use date literals and time literals, such as #Feb 12, 1969# and #4:45:23 PM#, instead.

```
Dim MyDateString, MyTimeString As String
Dim MyDate, MyTime As Date
MyDateString = "February 12, 1969"
MyTimeString = "4:35:47 PM"
' ...
MyDate = CDate(MyDateString)   ' Convert to Date data type.
MyTime = CDate(MyTimeString)   ' Convert to Date data type.
```

CDbl Example

This example uses the **CDbl** function to convert an expression to **Double**.

```
Dim MyDec As Decimal
Dim MyDouble As Double
MyDec = 234.456784D    ' Literal type character D makes MyDec a Decimal.
MyDouble = CDbl(MyDec * 8.2D * 0.01D)   ' Convert result to a Double.
```

CDec Example

This example uses the **CDec** function to convert a numeric value to **Decimal**.

```
Dim MyDouble As Double
Dim MyDecimal As Decimal
MyDouble = 10000000.0587
MyDecimal = CDec(MyDouble)   ' Convert to Decimal.
```

CInt Example

This example uses the **CInt** function to convert a value to **Integer**.

```
Dim MyDouble As Double
Dim MyInt As Integer
MyDouble = 2345.5678
MyInt = CInt(MyDouble)   ' MyInt is set to 2346.
```

CLng Example

This example uses the **CLng** function to convert values to **Long**.

```
Dim MyDbl1, MyDbl2 As Double
Dim MyLong1, MyLong2 As Long
MyDbl1 = 25427.45
MyDbl2 = 25427.55
MyLong1 = CLng(MyDbl1)   ' MyLong1 contains 25427.
MyLong2 = CLng(MyDbl2)   ' MyLong2 contains 25428.
```

CObj Example

This example uses the **CObj** function to convert a numeric value to **Object**. The **Object** variable itself contains only a four-byte pointer, which points to the **Double** value assigned to it.

```
Dim MyDouble As Double
Dim MyObject As Object
```

```
MyDouble = 2.7182818284
MyObject = CObj(MyDouble)   ' Double value is pointed to by MyObject.
```

CShort Example

This example uses the **CShort** function to convert a numeric value to **Short**.

```
Dim MyByte as Byte
Dim MyShort as Short
MyByte = 100
MyShort = CShort(MyByte)   ' Convert to Short.
```

CSng Example

This example uses the **CSng** function to convert values to **Single**.

```
Dim MyDouble1, MyDouble2 As Double
Dim MySingle1, MySingle2 As Single
MyDouble1 = 75.3421105
MyDouble2 = 75.3421567
MySingle1 = CSng(MyDouble1)   ' MySingle1 is set to 75.34211.
MySingle2 = CSng(MyDouble2)   ' MySingle2 is set to 75.34216.
```

CStr Example

This example uses the **CStr** function to convert a numeric value to **String**.

```
Dim MyDouble As Double
Dim MyString As String
MyDouble = 437.324
MyString = CStr(MyDouble)   ' MyString is set to "437.324".
```

This example uses the **CStr** function to convert **Date** values to **String** values.

```
Dim MyDate As Date
Dim MyString As String
' ...
MyDate = #February 12, 1969 00:00:00#   ' INVALID format.
' Date literals must be in the format #m/d/yyyy# or they are invalid.
' ...
MyDate = #2/12/69 00:00:00#   ' Time is midnight.
' The neutral time value of 00:00:00 is suppressed in the conversion.
MyString = CStr(MyDate)   ' MyString is set to "2/12/1969".
' ...
MyDate = #2/12/69 00:00:01#   ' Time is one second past midnight.
' The time component becomes part of the converted value.
MyString = CStr(MyDate)   ' MyString is set to "2/12/1969 12:00:01 AM".
```

CStr always renders a **Date** value in the standard short format for the current locale, for example, "6/15/2003 4:35:47 PM".

Type Conversion Functions

These functions are compiled inline, meaning the conversion code is part of the code that evaluates the expression. Execution is faster because there is no call to a procedure to accomplish the conversion. Each function coerces an expression to a specific data type.

```
CBool(expression)
CByte(expression)
CChar(expression)
CDate(expression)
CDbl(expression)
CDec(expression)
CInt(expression)
CLng(expression)
CObj(expression)
CShort(expression)
CSng(expression)
CStr(expression)
```

Part

expression
Required. Any **String** expression or numeric expression.

Return Types

The function name determines the return type, as shown in the following table:

Function name	Return type	Range for *expression* argument
CBool	**Boolean**	Any valid **String** or numeric expression.
CByte	**Byte**	0 through 255; fractions are rounded.
CChar	**Char**	Any valid **String** expression; value can be 0 through 65535.
CDate	**Date**	Any valid representation of a date and time.
CDbl	**Double**	-1.79769313486231E+308 through -4.94065645841247E-324 for negative values; 4.94065645841247E-324 through 1.79769313486231E+308 for positive values.
CDec	**Decimal**	+/-79,228,162,514,264,337,593,543,950,335 for zero-scaled numbers, that is, numbers with no decimal places. For numbers with 28 decimal places, the range is +/-7.9228162514264337593543950335. The smallest possible non-zero number is 0.0000000000000000000000000001.
CInt	**Integer**	-2,147,483,648 through 2,147,483,647; fractions are rounded.
CLng	**Long**	-9,223,372,036,854,775,808 through 9,223,372,036,854,775,807; fractions are rounded.
CObj	**Object**	Any valid expression.
CShort	**Short**	-32,768 through 32,767; fractions are rounded.
CSng	**Single**	-3.402823E+38 through -1.401298E-45 for negative values; 1.401298E-45 through 3.402823E+38 for positive values.
CStr	**String**	Returns for **CStr** depend on the *expression* argument. See Returns for CStr.

Remarks

If the *expression* passed to the function is outside the range of the data type to which it is being converted, an error occurs.

In general, you can use the data type conversion functions to force the result of some operation to a particular data type rather than the default data type. For example, use **CDec** to force decimal arithmetic in cases where single-precision, double-precision, or integer arithmetic normally would occur.

When the fractional part is exactly 0.5, **CInt** and **CLng** always round it to the nearest even number. For example, 0.5 rounds to 0

and 1.5 rounds to 2. **CInt** and **CLng** differ from the **Fix** and **Int** functions, which truncate, rather than round, the fractional part of a number. Also, **Fix** and **Int** always return a value of the same type as is passed in.

Use the **IsDate** function to determine if a value can be converted to a date and time. **CDate** recognizes date literals and time literals as well as numbers that fall within the range of acceptable dates.

CDate recognizes date formats according to the locale setting of your system. You must provide the day, month, and year in the correct order for your locale, or the date may not be interpreted correctly. A long date format is not recognized if it contains a day-of-the-week string, such as "Wednesday".

The **Date** data type always contains both date and time information. For purposes of type conversion, Visual Basic .NET considers 1/1/1 (January 1 of the year 1) to be a neutral value for the date, and 00:00:00 (midnight) to be a neutral value for the time. If you convert a **Date** value to a string, **CStr** does not include neutral values in the resulting string. For example, if you convert `#January 1, 0001 9:30:00#` to a string, the result is "9:30:00 AM"; the date information is suppressed. However, the date information is still present in the original **Date** value and can be recovered with functions such as **DatePart**.

The **CType** function takes a second argument, *typename*, and coerces *expression* to *typename*, where *typename* can be any data type, structure, class, or interface. For more information, see CType Function.

CBool Example

This example uses the **CBool** function to convert expressions to **Boolean** values. If an expression evaluates to a nonzero value, **CBool** returns **True**; otherwise, it returns **False**.

```
Dim A, B, C As Integer
Dim Check As Boolean
A = 5
B = 5
Check = CBool(A = B)   ' Check is set to True.
' ...
C = 0
Check = CBool(C)   ' Check is set to False.
```

CByte Example

This example uses the **CByte** function to convert an expression to a **Byte**.

```
Dim MyDouble As Double
Dim MyByte As Byte
MyDouble = 125.5678
MyByte = CByte(MyDouble)   ' MyByte is set to 126.
```

CChar Example

This example uses the **CChar** function to convert a the first character of a **String** expression to a **Char** type.

```
Dim MyString As String
Dim MyChar As Char
MyString = "BCD"   ' CChar converts only first character of string.
MyChar = CChar(MyString)   ' MyChar is set to "B".
```

The input argument to **CChar** must be of data type **String**. You cannot use **CChar** to convert a number to a character, because **CChar** cannot accept a numeric data type. This example obtains a number representing a code point (character code) and converts it to the corresponding character. It uses **InputBox** to obtain the string of digits, **CInt** to convert the string to type **Integer**, and **ChrW** to convert the number to type **Char**.

```
Dim MyDigits As String   ' Input string of digits to be converted.
Dim CodePoint As Integer   ' Number to be represented as a character.
Dim MyChar As Char
MyDigits = InputBox("Enter code point of character:")
CodePoint = CInt(MyDigits)   ' Convert entire string to Integer.
MyChar = ChrW(CodePoint)   ' MyChar is set to Char value of code point.
```

CDate Example

This example uses the **CDate** function to convert strings to **Date** values. In general, hard-coding dates and times as strings (as shown in this example) is not recommended. Use date literals and time literals, such as #Feb 12, 1969# and #4:45:23 PM#, instead.

```
Dim MyDateString, MyTimeString As String
Dim MyDate, MyTime As Date
MyDateString = "February 12, 1969"
MyTimeString = "4:35:47 PM"
' ...
MyDate = CDate(MyDateString)   ' Convert to Date data type.
MyTime = CDate(MyTimeString)   ' Convert to Date data type.
```

CDbl Example

This example uses the **CDbl** function to convert an expression to **Double**.

```
Dim MyDec As Decimal
Dim MyDouble As Double
MyDec = 234.456784D    ' Literal type character D makes MyDec a Decimal.
MyDouble = CDbl(MyDec * 8.2D * 0.01D)   ' Convert result to a Double.
```

CDec Example

This example uses the **CDec** function to convert a numeric value to **Decimal**.

```
Dim MyDouble As Double
Dim MyDecimal As Decimal
MyDouble = 10000000.0587
MyDecimal = CDec(MyDouble)   ' Convert to Decimal.
```

CInt Example

This example uses the **CInt** function to convert a value to **Integer**.

```
Dim MyDouble As Double
Dim MyInt As Integer
MyDouble = 2345.5678
MyInt = CInt(MyDouble)   ' MyInt is set to 2346.
```

CLng Example

This example uses the **CLng** function to convert values to **Long**.

```
Dim MyDbl1, MyDbl2 As Double
Dim MyLong1, MyLong2 As Long
MyDbl1 = 25427.45
MyDbl2 = 25427.55
MyLong1 = CLng(MyDbl1)   ' MyLong1 contains 25427.
MyLong2 = CLng(MyDbl2)   ' MyLong2 contains 25428.
```

CObj Example

This example uses the **CObj** function to convert a numeric value to **Object**. The **Object** variable itself contains only a four-byte pointer, which points to the **Double** value assigned to it.

```
Dim MyDouble As Double
Dim MyObject As Object
```

```
MyDouble = 2.7182818284
MyObject = CObj(MyDouble)   ' Double value is pointed to by MyObject.
```

CShort Example

This example uses the **CShort** function to convert a numeric value to **Short**.

```
Dim MyByte as Byte
Dim MyShort as Short
MyByte = 100
MyShort = CShort(MyByte)   ' Convert to Short.
```

CSng Example

This example uses the **CSng** function to convert values to **Single**.

```
Dim MyDouble1, MyDouble2 As Double
Dim MySingle1, MySingle2 As Single
MyDouble1 = 75.3421105
MyDouble2 = 75.3421567
MySingle1 = CSng(MyDouble1)   ' MySingle1 is set to 75.34211.
MySingle2 = CSng(MyDouble2)   ' MySingle2 is set to 75.34216.
```

CStr Example

This example uses the **CStr** function to convert a numeric value to **String**.

```
Dim MyDouble As Double
Dim MyString As String
MyDouble = 437.324
MyString = CStr(MyDouble)   ' MyString is set to "437.324".
```

This example uses the **CStr** function to convert **Date** values to **String** values.

```
Dim MyDate As Date
Dim MyString As String
' ...
MyDate = #February 12, 1969 00:00:00#   ' INVALID format.
' Date literals must be in the format #m/d/yyyy# or they are invalid.
' ...
MyDate = #2/12/69 00:00:00#   ' Time is midnight.
' The neutral time value of 00:00:00 is suppressed in the conversion.
MyString = CStr(MyDate)   ' MyString is set to "2/12/1969".
' ...
MyDate = #2/12/69 00:00:01#   ' Time is one second past midnight.
' The time component becomes part of the converted value.
MyString = CStr(MyDate)   ' MyString is set to "2/12/1969 12:00:01 AM".
```

CStr always renders a **Date** value in the standard short format for the current locale, for example, "6/15/2003 4:35:47 PM".

Type Conversion Functions

These functions are compiled inline, meaning the conversion code is part of the code that evaluates the expression. Execution is faster because there is no call to a procedure to accomplish the conversion. Each function coerces an expression to a specific data type.

```
CBool(expression)
CByte(expression)
CChar(expression)
CDate(expression)
CDbl(expression)
CDec(expression)
CInt(expression)
CLng(expression)
CObj(expression)
CShort(expression)
CSng(expression)
CStr(expression)
```

Part

expression
Required. Any **String** expression or numeric expression.

Return Types

The function name determines the return type, as shown in the following table:

Function name	Return type	Range for *expression* argument
CBool	**Boolean**	Any valid **String** or numeric expression.
CByte	**Byte**	0 through 255; fractions are rounded.
CChar	**Char**	Any valid **String** expression; value can be 0 through 65535.
CDate	**Date**	Any valid representation of a date and time.
CDbl	**Double**	-1.79769313486231E+308 through -4.94065645841247E-324 for negative values; 4.94065645841247E-324 through 1.79769313486231E+308 for positive values.
CDec	**Decimal**	+/-79,228,162,514,264,337,593,543,950,335 for zero-scaled numbers, that is, numbers with no decimal places. For numbers with 28 decimal places, the range is +/-7.9228162514264337593543950335. The smallest possible non-zero number is 0.0000000000000000000000000001.
CInt	**Integer**	-2,147,483,648 through 2,147,483,647; fractions are rounded.
CLng	**Long**	-9,223,372,036,854,775,808 through 9,223,372,036,854,775,807; fractions are rounded.
CObj	**Object**	Any valid expression.
CShort	**Short**	-32,768 through 32,767; fractions are rounded.
CSng	**Single**	-3.402823E+38 through -1.401298E-45 for negative values; 1.401298E-45 through 3.402823E+38 for positive values.
CStr	**String**	Returns for **CStr** depend on the *expression* argument. See Returns for CStr.

Remarks

If the *expression* passed to the function is outside the range of the data type to which it is being converted, an error occurs.

In general, you can use the data type conversion functions to force the result of some operation to a particular data type rather than the default data type. For example, use **CDec** to force decimal arithmetic in cases where single-precision, double-precision, or integer arithmetic normally would occur.

When the fractional part is exactly 0.5, **CInt** and **CLng** always round it to the nearest even number. For example, 0.5 rounds to 0

and 1.5 rounds to 2. **CInt** and **CLng** differ from the **Fix** and **Int** functions, which truncate, rather than round, the fractional part of a number. Also, **Fix** and **Int** always return a value of the same type as is passed in.

Use the **IsDate** function to determine if a value can be converted to a date and time. **CDate** recognizes date literals and time literals as well as numbers that fall within the range of acceptable dates.

CDate recognizes date formats according to the locale setting of your system. You must provide the day, month, and year in the correct order for your locale, or the date may not be interpreted correctly. A long date format is not recognized if it contains a day-of-the-week string, such as "Wednesday".

The **Date** data type always contains both date and time information. For purposes of type conversion, Visual Basic .NET considers 1/1/1 (January 1 of the year 1) to be a neutral value for the date, and 00:00:00 (midnight) to be a neutral value for the time. If you convert a **Date** value to a string, **CStr** does not include neutral values in the resulting string. For example, if you convert `#January 1, 0001 9:30:00#` to a string, the result is "9:30:00 AM"; the date information is suppressed. However, the date information is still present in the original **Date** value and can be recovered with functions such as **DatePart**.

The **CType** function takes a second argument, *typename*, and coerces *expression* to *typename*, where *typename* can be any data type, structure, class, or interface. For more information, see CType Function.

CBool Example

This example uses the **CBool** function to convert expressions to **Boolean** values. If an expression evaluates to a nonzero value, **CBool** returns **True**; otherwise, it returns **False**.

```
Dim A, B, C As Integer
Dim Check As Boolean
A = 5
B = 5
Check = CBool(A = B)   ' Check is set to True.
' ...
C = 0
Check = CBool(C)   ' Check is set to False.
```

CByte Example

This example uses the **CByte** function to convert an expression to a **Byte**.

```
Dim MyDouble As Double
Dim MyByte As Byte
MyDouble = 125.5678
MyByte = CByte(MyDouble)   ' MyByte is set to 126.
```

CChar Example

This example uses the **CChar** function to convert a the first character of a **String** expression to a **Char** type.

```
Dim MyString As String
Dim MyChar As Char
MyString = "BCD"   ' CChar converts only first character of string.
MyChar = CChar(MyString)   ' MyChar is set to "B".
```

The input argument to **CChar** must be of data type **String**. You cannot use **CChar** to convert a number to a character, because **CChar** cannot accept a numeric data type. This example obtains a number representing a code point (character code) and converts it to the corresponding character. It uses **InputBox** to obtain the string of digits, **CInt** to convert the string to type **Integer**, and **ChrW** to convert the number to type **Char**.

```
Dim MyDigits As String   ' Input string of digits to be converted.
Dim CodePoint As Integer   ' Number to be represented as a character.
Dim MyChar As Char
MyDigits = InputBox("Enter code point of character:")
CodePoint = CInt(MyDigits)   ' Convert entire string to Integer.
MyChar = ChrW(CodePoint)   ' MyChar is set to Char value of code point.
```

CDate Example

This example uses the **CDate** function to convert strings to **Date** values. In general, hard-coding dates and times as strings (as shown in this example) is not recommended. Use date literals and time literals, such as #Feb 12, 1969# and #4:45:23 PM#, instead.

```
Dim MyDateString, MyTimeString As String
Dim MyDate, MyTime As Date
MyDateString = "February 12, 1969"
MyTimeString = "4:35:47 PM"
' ...
MyDate = CDate(MyDateString)   ' Convert to Date data type.
MyTime = CDate(MyTimeString)   ' Convert to Date data type.
```

CDbl Example

This example uses the **CDbl** function to convert an expression to **Double**.

```
Dim MyDec As Decimal
Dim MyDouble As Double
MyDec = 234.456784D    ' Literal type character D makes MyDec a Decimal.
MyDouble = CDbl(MyDec * 8.2D * 0.01D)   ' Convert result to a Double.
```

CDec Example

This example uses the **CDec** function to convert a numeric value to **Decimal**.

```
Dim MyDouble As Double
Dim MyDecimal As Decimal
MyDouble = 10000000.0587
MyDecimal = CDec(MyDouble)   ' Convert to Decimal.
```

CInt Example

This example uses the **CInt** function to convert a value to **Integer**.

```
Dim MyDouble As Double
Dim MyInt As Integer
MyDouble = 2345.5678
MyInt = CInt(MyDouble)   ' MyInt is set to 2346.
```

CLng Example

This example uses the **CLng** function to convert values to **Long**.

```
Dim MyDbl1, MyDbl2 As Double
Dim MyLong1, MyLong2 As Long
MyDbl1 = 25427.45
MyDbl2 = 25427.55
MyLong1 = CLng(MyDbl1)   ' MyLong1 contains 25427.
MyLong2 = CLng(MyDbl2)   ' MyLong2 contains 25428.
```

CObj Example

This example uses the **CObj** function to convert a numeric value to **Object**. The **Object** variable itself contains only a four-byte pointer, which points to the **Double** value assigned to it.

```
Dim MyDouble As Double
Dim MyObject As Object
```

```
MyDouble = 2.7182818284
MyObject = CObj(MyDouble)   ' Double value is pointed to by MyObject.
```

CShort Example

This example uses the **CShort** function to convert a numeric value to **Short**.

```
Dim MyByte as Byte
Dim MyShort as Short
MyByte = 100
MyShort = CShort(MyByte)   ' Convert to Short.
```

CSng Example

This example uses the **CSng** function to convert values to **Single**.

```
Dim MyDouble1, MyDouble2 As Double
Dim MySingle1, MySingle2 As Single
MyDouble1 = 75.3421105
MyDouble2 = 75.3421567
MySingle1 = CSng(MyDouble1)   ' MySingle1 is set to 75.34211.
MySingle2 = CSng(MyDouble2)   ' MySingle2 is set to 75.34216.
```

CStr Example

This example uses the **CStr** function to convert a numeric value to **String**.

```
Dim MyDouble As Double
Dim MyString As String
MyDouble = 437.324
MyString = CStr(MyDouble)   ' MyString is set to "437.324".
```

This example uses the **CStr** function to convert **Date** values to **String** values.

```
Dim MyDate As Date
Dim MyString As String
' ...
MyDate = #February 12, 1969 00:00:00#   ' INVALID format.
' Date literals must be in the format #m/d/yyyy# or they are invalid.
' ...
MyDate = #2/12/69 00:00:00#   ' Time is midnight.
' The neutral time value of 00:00:00 is suppressed in the conversion.
MyString = CStr(MyDate)   ' MyString is set to "2/12/1969".
' ...
MyDate = #2/12/69 00:00:01#   ' Time is one second past midnight.
' The time component becomes part of the converted value.
MyString = CStr(MyDate)   ' MyString is set to "2/12/1969 12:00:01 AM".
```

CStr always renders a **Date** value in the standard short format for the current locale, for example, "6/15/2003 4:35:47 PM".

Type Conversion Functions

These functions are compiled inline, meaning the conversion code is part of the code that evaluates the expression. Execution is faster because there is no call to a procedure to accomplish the conversion. Each function coerces an expression to a specific data type.

```
CBool(expression)
CByte(expression)
CChar(expression)
CDate(expression)
CDbl(expression)
CDec(expression)
CInt(expression)
CLng(expression)
CObj(expression)
CShort(expression)
CSng(expression)
CStr(expression)
```

Part

expression
Required. Any **String** expression or numeric expression.

Return Types

The function name determines the return type, as shown in the following table:

Function name	Return type	Range for *expression* argument
CBool	**Boolean**	Any valid **String** or numeric expression.
CByte	**Byte**	0 through 255; fractions are rounded.
CChar	**Char**	Any valid **String** expression; value can be 0 through 65535.
CDate	**Date**	Any valid representation of a date and time.
CDbl	**Double**	-1.79769313486231E+308 through -4.94065645841247E-324 for negative values; 4.94065645841247E-324 through 1.79769313486231E+308 for positive values.
CDec	**Decimal**	+/-79,228,162,514,264,337,593,543,950,335 for zero-scaled numbers, that is, numbers with no decimal places. For numbers with 28 decimal places, the range is +/-7.9228162514264337593543950335. The smallest possible non-zero number is 0.0000000000000000000000000001.
CInt	**Integer**	-2,147,483,648 through 2,147,483,647; fractions are rounded.
CLng	**Long**	-9,223,372,036,854,775,808 through 9,223,372,036,854,775,807; fractions are rounded.
CObj	**Object**	Any valid expression.
CShort	**Short**	-32,768 through 32,767; fractions are rounded.
CSng	**Single**	-3.402823E+38 through -1.401298E-45 for negative values; 1.401298E-45 through 3.402823E+38 for positive values.
CStr	**String**	Returns for **CStr** depend on the *expression* argument. See Returns for CStr.

Remarks

If the *expression* passed to the function is outside the range of the data type to which it is being converted, an error occurs.

In general, you can use the data type conversion functions to force the result of some operation to a particular data type rather than the default data type. For example, use **CDec** to force decimal arithmetic in cases where single-precision, double-precision, or integer arithmetic normally would occur.

When the fractional part is exactly 0.5, **CInt** and **CLng** always round it to the nearest even number. For example, 0.5 rounds to 0

and 1.5 rounds to 2. **CInt** and **CLng** differ from the **Fix** and **Int** functions, which truncate, rather than round, the fractional part of a number. Also, **Fix** and **Int** always return a value of the same type as is passed in.

Use the **IsDate** function to determine if a value can be converted to a date and time. **CDate** recognizes date literals and time literals as well as numbers that fall within the range of acceptable dates.

CDate recognizes date formats according to the locale setting of your system. You must provide the day, month, and year in the correct order for your locale, or the date may not be interpreted correctly. A long date format is not recognized if it contains a day-of-the-week string, such as "Wednesday".

The **Date** data type always contains both date and time information. For purposes of type conversion, Visual Basic .NET considers 1/1/1 (January 1 of the year 1) to be a neutral value for the date, and 00:00:00 (midnight) to be a neutral value for the time. If you convert a **Date** value to a string, **CStr** does not include neutral values in the resulting string. For example, if you convert `#January 1, 0001 9:30:00#` to a string, the result is "9:30:00 AM"; the date information is suppressed. However, the date information is still present in the original **Date** value and can be recovered with functions such as **DatePart**.

The **CType** function takes a second argument, *typename*, and coerces *expression* to *typename*, where *typename* can be any data type, structure, class, or interface. For more information, see CType Function.

CBool Example

This example uses the **CBool** function to convert expressions to **Boolean** values. If an expression evaluates to a nonzero value, **CBool** returns **True**; otherwise, it returns **False**.

```
Dim A, B, C As Integer
Dim Check As Boolean
A = 5
B = 5
Check = CBool(A = B)   ' Check is set to True.
' ...
C = 0
Check = CBool(C)   ' Check is set to False.
```

CByte Example

This example uses the **CByte** function to convert an expression to a **Byte**.

```
Dim MyDouble As Double
Dim MyByte As Byte
MyDouble = 125.5678
MyByte = CByte(MyDouble)   ' MyByte is set to 126.
```

CChar Example

This example uses the **CChar** function to convert a the first character of a **String** expression to a **Char** type.

```
Dim MyString As String
Dim MyChar As Char
MyString = "BCD"   ' CChar converts only first character of string.
MyChar = CChar(MyString)   ' MyChar is set to "B".
```

The input argument to **CChar** must be of data type **String**. You cannot use **CChar** to convert a number to a character, because **CChar** cannot accept a numeric data type. This example obtains a number representing a code point (character code) and converts it to the corresponding character. It uses **InputBox** to obtain the string of digits, **CInt** to convert the string to type **Integer**, and **ChrW** to convert the number to type **Char**.

```
Dim MyDigits As String   ' Input string of digits to be converted.
Dim CodePoint As Integer   ' Number to be represented as a character.
Dim MyChar As Char
MyDigits = InputBox("Enter code point of character:")
CodePoint = CInt(MyDigits)   ' Convert entire string to Integer.
MyChar = ChrW(CodePoint)   ' MyChar is set to Char value of code point.
```

CDate Example

This example uses the **CDate** function to convert strings to **Date** values. In general, hard-coding dates and times as strings (as shown in this example) is not recommended. Use date literals and time literals, such as #Feb 12, 1969# and #4:45:23 PM#, instead.

```
Dim MyDateString, MyTimeString As String
Dim MyDate, MyTime As Date
MyDateString = "February 12, 1969"
MyTimeString = "4:35:47 PM"
' ...
MyDate = CDate(MyDateString)   ' Convert to Date data type.
MyTime = CDate(MyTimeString)   ' Convert to Date data type.
```

CDbl Example

This example uses the **CDbl** function to convert an expression to **Double**.

```
Dim MyDec As Decimal
Dim MyDouble As Double
MyDec = 234.456784D    ' Literal type character D makes MyDec a Decimal.
MyDouble = CDbl(MyDec * 8.2D * 0.01D)   ' Convert result to a Double.
```

CDec Example

This example uses the **CDec** function to convert a numeric value to **Decimal**.

```
Dim MyDouble As Double
Dim MyDecimal As Decimal
MyDouble = 10000000.0587
MyDecimal = CDec(MyDouble)   ' Convert to Decimal.
```

CInt Example

This example uses the **CInt** function to convert a value to **Integer**.

```
Dim MyDouble As Double
Dim MyInt As Integer
MyDouble = 2345.5678
MyInt = CInt(MyDouble)   ' MyInt is set to 2346.
```

CLng Example

This example uses the **CLng** function to convert values to **Long**.

```
Dim MyDbl1, MyDbl2 As Double
Dim MyLong1, MyLong2 As Long
MyDbl1 = 25427.45
MyDbl2 = 25427.55
MyLong1 = CLng(MyDbl1)   ' MyLong1 contains 25427.
MyLong2 = CLng(MyDbl2)   ' MyLong2 contains 25428.
```

CObj Example

This example uses the **CObj** function to convert a numeric value to **Object**. The **Object** variable itself contains only a four-byte pointer, which points to the **Double** value assigned to it.

```
Dim MyDouble As Double
Dim MyObject As Object
```

```
MyDouble = 2.7182818284
MyObject = CObj(MyDouble)   ' Double value is pointed to by MyObject.
```

CShort Example

This example uses the **CShort** function to convert a numeric value to **Short**.

```
Dim MyByte as Byte
Dim MyShort as Short
MyByte = 100
MyShort = CShort(MyByte)   ' Convert to Short.
```

CSng Example

This example uses the **CSng** function to convert values to **Single**.

```
Dim MyDouble1, MyDouble2 As Double
Dim MySingle1, MySingle2 As Single
MyDouble1 = 75.3421105
MyDouble2 = 75.3421567
MySingle1 = CSng(MyDouble1)   ' MySingle1 is set to 75.34211.
MySingle2 = CSng(MyDouble2)   ' MySingle2 is set to 75.34216.
```

CStr Example

This example uses the **CStr** function to convert a numeric value to **String**.

```
Dim MyDouble As Double
Dim MyString As String
MyDouble = 437.324
MyString = CStr(MyDouble)   ' MyString is set to "437.324".
```

This example uses the **CStr** function to convert **Date** values to **String** values.

```
Dim MyDate As Date
Dim MyString As String
' ...
MyDate = #February 12, 1969 00:00:00#   ' INVALID format.
' Date literals must be in the format #m/d/yyyy# or they are invalid.
' ...
MyDate = #2/12/69 00:00:00#   ' Time is midnight.
' The neutral time value of 00:00:00 is suppressed in the conversion.
MyString = CStr(MyDate)   ' MyString is set to "2/12/1969".
' ...
MyDate = #2/12/69 00:00:01#   ' Time is one second past midnight.
' The time component becomes part of the converted value.
MyString = CStr(MyDate)   ' MyString is set to "2/12/1969 12:00:01 AM".
```

CStr always renders a **Date** value in the standard short format for the current locale, for example, "6/15/2003 4:35:47 PM".

ChDir Function

Changes the current directory or folder.

```
Public Sub ChDir(ByVal Path As String)
```

Parameter

Path
Required. A **String** expression that identifies which directory or folder becomes the new default directory or folder. *Path* may include the drive. If no drive is specified, **ChDir** changes the default directory or folder on the current drive.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	52	*Path* is empty.
FileNotFoundException	76	Invalid drive is specified, or drive is unavail able.

Remarks

The **ChDir** function changes the default directory, but not the default drive. For example, if the default drive is C, the following statement changes the default directory on drive D, but C remains the default drive:

```
ChDir("D:\TMP")
```

Making relative directory changes is accomplished using "..", as follows:

```
ChDir("..") ' Moves up one directory.
```

Security Note The **ChDir** function requires unmanaged code permission, which may affect its execution in partial trust situations. For more information, see SecurityPermission Class and Code Access Permissions.

Example

This example uses the **ChDir** function to change the current directory or folder.

```
' Change current directory or folder to "MYDIR".
ChDir("MYDIR")

' Assume "C:" is the current drive. The following statement changes
' the default directory on drive "D:". "C:" remains the current drive.
ChDir("D:\WINDOWS\SYSTEM")
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in MicrosoftVisualBasic.dll)

See Also

ChDrive Function | CurDir Function | Dir Function | MkDir Function | RmDir Function | ArgumentException Class | FileNotFoundException Class

ChDrive Function

Changes the current drive.

```
Public Overloads Sub ChDrive(ByVal Drive As { Char | String })
```

Parameter

Drive
Required. String expression that specifies an existing drive. If you supply a zero-length string (""), the current drive doesn't change. If the *Drive* argument is a multiple-character string, **ChDrive** uses only the first letter.

Exceptions/Errors

Exception type	Error number	Condition
IOException	68	Invalid drive is specified, or drive is unavailable.

Remarks

The **ChDrive** function requires unmanaged code permission, which may affect its execution in partial trust situations. For more information, see SecurityPermission Class and Code Access Permissions.

Example

This example uses the **ChDrive** function to change the current drive. The function throws an exception if the drive does not exist.

```
ChDrive("D")   ' Make "D" the current drive.
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in MicrosoftVisualBasic.dll)

See Also

ChDir Function | CurDir Function | MkDir Function | RmDir Function | IOException Class

Choose Function

Selects and returns a value from a list of arguments.

```
Public Function Choose( _
   ByVal Index As Double, _
   ByVal ParamArray Choice() As Object _
) As Object
```

Parameters

Index
Required. **Double**. Numeric expression that results in a value between 1 and the number of elements passed in the *Choice* argument.

Choice()
Required. **Object** parameter array. You can supply either a single variable or an expression that evaluates to the **Object** data type, to a list of **Object** variables or expressions separated by commas, or to a single-dimensional array of **Object** elements.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	Rank of *Choice()* <> 1 .

Remarks

The **Choose** function returns a member of the list passed in *Choice()*, based on the value of *Index*. The first member of the list is selected when *Index* is 1. The last member of the list is selected when *Index* is **UBound**(*Choice()*). If *Index* is outside these limits, **Choose** returns **Nothing**.

If *Index* is not a whole number, it is rounded to the nearest whole number before being evaluated.

You can use **Choose** to look up a value in a list of possibilities.

> **Note** The expressions in the argument list can include function calls. As part of preparing the argument list for the call to **Choose**, the Visual Basic compiler calls every function in every expression. This means that you cannot rely on a particular function not being called if a different expression is selected by *Index*.

Example

This example uses the **Choose** function to display a name in response to an index passed into the procedure in the `Ind` parameter.

```
Function GetChoice(Ind As Integer) As String
   GetChoice = CStr(Choose(Ind, "Speedy", "United", "Federal"))
End Function
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Interaction

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

IIf Function | Select...Case Statements | Switch Function

Chr, ChrW Functions

Returns the character associated with the specified character code.

```
Public Function Chr(ByVal CharCode As Integer) As Char
Public Function ChrW(ByVal CharCode As Integer) As Char
```

Parameter

CharCode
Required. An **Integer** expression representing the *code point*, or character code, for the character. If *CharCode* is outside the range -32768 through 65535, an **ArgumentException** error occurs.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*CharCode* < -32768 or > 65535 .

Remarks

The asymmetric range accepted for *CharCode* compensates for the storage differences between the **Short** and **Integer** data types. For example, &H8E01 is -29183 as a **Short** but +36353 as an **Integer**. This also facilitates compatibility with Visual Basic 6.0.

Chr uses the **Encoding** class in the **System.Text** namespace to determine if the current thread is using a single-byte character set (SBCS) or a double-byte character set (DBCS). It then takes *CharCode* as a code point in the appropriate set. The range can be 0 through 255 for SBCS characters and -32768 through 65535 for DBCS characters. The returned character depends on the code page for the current thread, which is contained in the **ANSICodePage** property of the **TextInfo** class. **TextInfo.ANSICodePage** can be obtained by specifying **System.Globalization.CultureInfo.CurrentCulture.TextInfo.ANSICodePage**.

ChrW takes *CharCode* as a Unicode code point. The range is independent of the culture and code page settings for the current thread. Values from -32768 through -1 are treated the same as values in the range +32768 through +65535.

Numbers from 0 through 31 are the same as standard, nonprintable ASCII codes. For example, `Chr(10)` returns a linefeed character.

> **Note** **The ChrB function of earlier versions of Visual Basic returns a single byte. It is used primarily for converting strings in double-byte character set (DBCS) applications. All Visual Basic .NET strings are in Unicode, and ChrB is no longer supported**.

Example

This example uses the **Chr** function to return the character associated with the specified character code.

```
Dim MyChar As Char
MyChar = Chr(65)   ' Returns "A".
MyChar = Chr(97)   ' Returns "a".
MyChar = Chr(62)   ' Returns ">".
MyChar = Chr(37)   ' Returns "%".
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Asc, AscW Functions | Str Function | Conversion Functions | Type Conversion Functions | System.Text Namespace | Encoding Class | System.Globalization Namespace | CultureInfo Class | TextInfo.ANSICodePage Property | ArgumentException Class

Chr, ChrW Functions

Returns the character associated with the specified character code.

```
Public Function Chr(ByVal CharCode As Integer) As Char
Public Function ChrW(ByVal CharCode As Integer) As Char
```

Parameter

CharCode
Required. An **Integer** expression representing the *code point*, or character code, for the character. If *CharCode* is outside the range -32768 through 65535, an **ArgumentException** error occurs.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*CharCode* < -32768 or > 65535 .

Remarks

The asymmetric range accepted for *CharCode* compensates for the storage differences between the **Short** and **Integer** data types. For example, &H8E01 is -29183 as a **Short** but +36353 as an **Integer**. This also facilitates compatibility with Visual Basic 6.0.

Chr uses the **Encoding** class in the **System.Text** namespace to determine if the current thread is using a single-byte character set (SBCS) or a double-byte character set (DBCS). It then takes *CharCode* as a code point in the appropriate set. The range can be 0 through 255 for SBCS characters and -32768 through 65535 for DBCS characters. The returned character depends on the code page for the current thread, which is contained in the **ANSICodePage** property of the **TextInfo** class. **TextInfo.ANSICodePage** can be obtained by specifying **System.Globalization.CultureInfo.CurrentCulture.TextInfo.ANSICodePage**.

ChrW takes *CharCode* as a Unicode code point. The range is independent of the culture and code page settings for the current thread. Values from -32768 through -1 are treated the same as values in the range +32768 through +65535.

Numbers from 0 through 31 are the same as standard, nonprintable ASCII codes. For example, `Chr(10)` returns a linefeed character.

> **Note** **The ChrB function of earlier versions of Visual Basic returns a single byte. It is used primarily for converting strings in double-byte character set (DBCS) applications. All Visual Basic .NET strings are in Unicode, and ChrB is no longer supported**.

Example

This example uses the **Chr** function to return the character associated with the specified character code.

```
Dim MyChar As Char
MyChar = Chr(65)   ' Returns "A".
MyChar = Chr(97)   ' Returns "a".
MyChar = Chr(62)   ' Returns ">".
MyChar = Chr(37)   ' Returns "%".
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Type Conversion Functions

These functions are compiled inline, meaning the conversion code is part of the code that evaluates the expression. Execution is faster because there is no call to a procedure to accomplish the conversion. Each function coerces an expression to a specific data type.

```
CBool(expression)
CByte(expression)
CChar(expression)
CDate(expression)
CDbl(expression)
CDec(expression)
CInt(expression)
CLng(expression)
CObj(expression)
CShort(expression)
CSng(expression)
CStr(expression)
```

Part

expression
Required. Any **String** expression or numeric expression.

Return Types

The function name determines the return type, as shown in the following table:

Function name	Return type	Range for *expression* argument
CBool	**Boolean**	Any valid **String** or numeric expression.
CByte	**Byte**	0 through 255; fractions are rounded.
CChar	**Char**	Any valid **String** expression; value can be 0 through 65535.
CDate	**Date**	Any valid representation of a date and time.
CDbl	**Double**	-1.79769313486231E+308 through -4.94065645841247E-324 for negative values; 4.94065645841247E-324 through 1.79769313486231E+308 for positive values.
CDec	**Decimal**	+/-79,228,162,514,264,337,593,543,950,335 for zero-scaled numbers, that is, numbers with no decimal places. For numbers with 28 decimal places, the range is +/-7.9228162514264337593543950335. The smallest possible non-zero number is 0.0000000000000000000000000001.
CInt	**Integer**	-2,147,483,648 through 2,147,483,647; fractions are rounded.
CLng	**Long**	-9,223,372,036,854,775,808 through 9,223,372,036,854,775,807; fractions are rounded.
CObj	**Object**	Any valid expression.
CShort	**Short**	-32,768 through 32,767; fractions are rounded.
CSng	**Single**	-3.402823E+38 through -1.401298E-45 for negative values; 1.401298E-45 through 3.402823E+38 for positive values.
CStr	**String**	Returns for **CStr** depend on the *expression* argument. See Returns for CStr.

Remarks

If the *expression* passed to the function is outside the range of the data type to which it is being converted, an error occurs.

In general, you can use the data type conversion functions to force the result of some operation to a particular data type rather than the default data type. For example, use **CDec** to force decimal arithmetic in cases where single-precision, double-precision, or integer arithmetic normally would occur.

When the fractional part is exactly 0.5, **CInt** and **CLng** always round it to the nearest even number. For example, 0.5 rounds to 0

and 1.5 rounds to 2. **CInt** and **CLng** differ from the **Fix** and **Int** functions, which truncate, rather than round, the fractional part of a number. Also, **Fix** and **Int** always return a value of the same type as is passed in.

Use the **IsDate** function to determine if a value can be converted to a date and time. **CDate** recognizes date literals and time literals as well as numbers that fall within the range of acceptable dates.

CDate recognizes date formats according to the locale setting of your system. You must provide the day, month, and year in the correct order for your locale, or the date may not be interpreted correctly. A long date format is not recognized if it contains a day-of-the-week string, such as "Wednesday".

The **Date** data type always contains both date and time information. For purposes of type conversion, Visual Basic .NET considers 1/1/1 (January 1 of the year 1) to be a neutral value for the date, and 00:00:00 (midnight) to be a neutral value for the time. If you convert a **Date** value to a string, **CStr** does not include neutral values in the resulting string. For example, if you convert `#January 1, 0001 9:30:00#` to a string, the result is "9:30:00 AM"; the date information is suppressed. However, the date information is still present in the original **Date** value and can be recovered with functions such as **DatePart**.

The **CType** function takes a second argument, *typename*, and coerces *expression* to *typename*, where *typename* can be any data type, structure, class, or interface. For more information, see CType Function.

CBool Example

This example uses the **CBool** function to convert expressions to **Boolean** values. If an expression evaluates to a nonzero value, **CBool** returns **True**; otherwise, it returns **False**.

```
Dim A, B, C As Integer
Dim Check As Boolean
A = 5
B = 5
Check = CBool(A = B)   ' Check is set to True.
' ...
C = 0
Check = CBool(C)   ' Check is set to False.
```

CByte Example

This example uses the **CByte** function to convert an expression to a **Byte**.

```
Dim MyDouble As Double
Dim MyByte As Byte
MyDouble = 125.5678
MyByte = CByte(MyDouble)   ' MyByte is set to 126.
```

CChar Example

This example uses the **CChar** function to convert a the first character of a **String** expression to a **Char** type.

```
Dim MyString As String
Dim MyChar As Char
MyString = "BCD"   ' CChar converts only first character of string.
MyChar = CChar(MyString)   ' MyChar is set to "B".
```

The input argument to **CChar** must be of data type **String**. You cannot use **CChar** to convert a number to a character, because **CChar** cannot accept a numeric data type. This example obtains a number representing a code point (character code) and converts it to the corresponding character. It uses **InputBox** to obtain the string of digits, **CInt** to convert the string to type **Integer**, and **ChrW** to convert the number to type **Char**.

```
Dim MyDigits As String   ' Input string of digits to be converted.
Dim CodePoint As Integer   ' Number to be represented as a character.
Dim MyChar As Char
MyDigits = InputBox("Enter code point of character:")
CodePoint = CInt(MyDigits)   ' Convert entire string to Integer.
MyChar = ChrW(CodePoint)   ' MyChar is set to Char value of code point.
```

CDate Example

This example uses the **CDate** function to convert strings to **Date** values. In general, hard-coding dates and times as strings (as shown in this example) is not recommended. Use date literals and time literals, such as #Feb 12, 1969# and #4:45:23 PM#, instead.

```
Dim MyDateString, MyTimeString As String
Dim MyDate, MyTime As Date
MyDateString = "February 12, 1969"
MyTimeString = "4:35:47 PM"
' ...
MyDate = CDate(MyDateString)   ' Convert to Date data type.
MyTime = CDate(MyTimeString)   ' Convert to Date data type.
```

CDbl Example

This example uses the **CDbl** function to convert an expression to **Double**.

```
Dim MyDec As Decimal
Dim MyDouble As Double
MyDec = 234.456784D    ' Literal type character D makes MyDec a Decimal.
MyDouble = CDbl(MyDec * 8.2D * 0.01D)   ' Convert result to a Double.
```

CDec Example

This example uses the **CDec** function to convert a numeric value to **Decimal**.

```
Dim MyDouble As Double
Dim MyDecimal As Decimal
MyDouble = 10000000.0587
MyDecimal = CDec(MyDouble)   ' Convert to Decimal.
```

CInt Example

This example uses the **CInt** function to convert a value to **Integer**.

```
Dim MyDouble As Double
Dim MyInt As Integer
MyDouble = 2345.5678
MyInt = CInt(MyDouble)   ' MyInt is set to 2346.
```

CLng Example

This example uses the **CLng** function to convert values to **Long**.

```
Dim MyDbl1, MyDbl2 As Double
Dim MyLong1, MyLong2 As Long
MyDbl1 = 25427.45
MyDbl2 = 25427.55
MyLong1 = CLng(MyDbl1)   ' MyLong1 contains 25427.
MyLong2 = CLng(MyDbl2)   ' MyLong2 contains 25428.
```

CObj Example

This example uses the **CObj** function to convert a numeric value to **Object**. The **Object** variable itself contains only a four-byte pointer, which points to the **Double** value assigned to it.

```
Dim MyDouble As Double
Dim MyObject As Object
```

```
MyDouble = 2.7182818284
MyObject = CObj(MyDouble)   ' Double value is pointed to by MyObject.
```

CShort Example

This example uses the **CShort** function to convert a numeric value to **Short**.

```
Dim MyByte as Byte
Dim MyShort as Short
MyByte = 100
MyShort = CShort(MyByte)   ' Convert to Short.
```

CSng Example

This example uses the **CSng** function to convert values to **Single**.

```
Dim MyDouble1, MyDouble2 As Double
Dim MySingle1, MySingle2 As Single
MyDouble1 = 75.3421105
MyDouble2 = 75.3421567
MySingle1 = CSng(MyDouble1)   ' MySingle1 is set to 75.34211.
MySingle2 = CSng(MyDouble2)   ' MySingle2 is set to 75.34216.
```

CStr Example

This example uses the **CStr** function to convert a numeric value to **String**.

```
Dim MyDouble As Double
Dim MyString As String
MyDouble = 437.324
MyString = CStr(MyDouble)   ' MyString is set to "437.324".
```

This example uses the **CStr** function to convert **Date** values to **String** values.

```
Dim MyDate As Date
Dim MyString As String
' ...
MyDate = #February 12, 1969 00:00:00#   ' INVALID format.
' Date literals must be in the format #m/d/yyyy# or they are invalid.
' ...
MyDate = #2/12/69 00:00:00#   ' Time is midnight.
' The neutral time value of 00:00:00 is suppressed in the conversion.
MyString = CStr(MyDate)   ' MyString is set to "2/12/1969".
' ...
MyDate = #2/12/69 00:00:01#   ' Time is one second past midnight.
' The time component becomes part of the converted value.
MyString = CStr(MyDate)   ' MyString is set to "2/12/1969 12:00:01 AM".
```

CStr always renders a **Date** value in the standard short format for the current locale, for example, "6/15/2003 4:35:47 PM".

Type Conversion Functions

These functions are compiled inline, meaning the conversion code is part of the code that evaluates the expression. Execution is faster because there is no call to a procedure to accomplish the conversion. Each function coerces an expression to a specific data type.

```
CBool(expression)
CByte(expression)
CChar(expression)
CDate(expression)
CDbl(expression)
CDec(expression)
CInt(expression)
CLng(expression)
CObj(expression)
CShort(expression)
CSng(expression)
CStr(expression)
```

Part

expression
Required. Any **String** expression or numeric expression.

Return Types

The function name determines the return type, as shown in the following table:

Function name	Return type	Range for *expression* argument
CBool	**Boolean**	Any valid **String** or numeric expression.
CByte	**Byte**	0 through 255; fractions are rounded.
CChar	**Char**	Any valid **String** expression; value can be 0 through 65535.
CDate	**Date**	Any valid representation of a date and time.
CDbl	**Double**	-1.79769313486231E+308 through -4.94065645841247E-324 for negative values; 4.94065645841247E-324 through 1.79769313486231E+308 for positive values.
CDec	**Decimal**	+/-79,228,162,514,264,337,593,543,950,335 for zero-scaled numbers, that is, numbers with no decimal places. For numbers with 28 decimal places, the range is +/-7.9228162514264337593543950335. The smallest possible non-zero number is 0.0000000000000000000000000001.
CInt	**Integer**	-2,147,483,648 through 2,147,483,647; fractions are rounded.
CLng	**Long**	-9,223,372,036,854,775,808 through 9,223,372,036,854,775,807; fractions are rounded.
CObj	**Object**	Any valid expression.
CShort	**Short**	-32,768 through 32,767; fractions are rounded.
CSng	**Single**	-3.402823E+38 through -1.401298E-45 for negative values; 1.401298E-45 through 3.402823E+38 for positive values.
CStr	**String**	Returns for **CStr** depend on the *expression* argument. See Returns for CStr.

Remarks

If the *expression* passed to the function is outside the range of the data type to which it is being converted, an error occurs.

In general, you can use the data type conversion functions to force the result of some operation to a particular data type rather than the default data type. For example, use **CDec** to force decimal arithmetic in cases where single-precision, double-precision, or integer arithmetic normally would occur.

When the fractional part is exactly 0.5, **CInt** and **CLng** always round it to the nearest even number. For example, 0.5 rounds to 0

and 1.5 rounds to 2. **CInt** and **CLng** differ from the **Fix** and **Int** functions, which truncate, rather than round, the fractional part of a number. Also, **Fix** and **Int** always return a value of the same type as is passed in.

Use the **IsDate** function to determine if a value can be converted to a date and time. **CDate** recognizes date literals and time literals as well as numbers that fall within the range of acceptable dates.

CDate recognizes date formats according to the locale setting of your system. You must provide the day, month, and year in the correct order for your locale, or the date may not be interpreted correctly. A long date format is not recognized if it contains a day-of-the-week string, such as "Wednesday".

The **Date** data type always contains both date and time information. For purposes of type conversion, Visual Basic .NET considers 1/1/1 (January 1 of the year 1) to be a neutral value for the date, and 00:00:00 (midnight) to be a neutral value for the time. If you convert a **Date** value to a string, **CStr** does not include neutral values in the resulting string. For example, if you convert `#January 1, 0001 9:30:00#` to a string, the result is "9:30:00 AM"; the date information is suppressed. However, the date information is still present in the original **Date** value and can be recovered with functions such as **DatePart**.

The **CType** function takes a second argument, *typename*, and coerces *expression* to *typename*, where *typename* can be any data type, structure, class, or interface. For more information, see CType Function.

CBool Example

This example uses the **CBool** function to convert expressions to **Boolean** values. If an expression evaluates to a nonzero value, **CBool** returns **True**; otherwise, it returns **False**.

```
Dim A, B, C As Integer
Dim Check As Boolean
A = 5
B = 5
Check = CBool(A = B)   ' Check is set to True.
' ...
C = 0
Check = CBool(C)   ' Check is set to False.
```

CByte Example

This example uses the **CByte** function to convert an expression to a **Byte**.

```
Dim MyDouble As Double
Dim MyByte As Byte
MyDouble = 125.5678
MyByte = CByte(MyDouble)   ' MyByte is set to 126.
```

CChar Example

This example uses the **CChar** function to convert a the first character of a **String** expression to a **Char** type.

```
Dim MyString As String
Dim MyChar As Char
MyString = "BCD"   ' CChar converts only first character of string.
MyChar = CChar(MyString)   ' MyChar is set to "B".
```

The input argument to **CChar** must be of data type **String**. You cannot use **CChar** to convert a number to a character, because **CChar** cannot accept a numeric data type. This example obtains a number representing a code point (character code) and converts it to the corresponding character. It uses **InputBox** to obtain the string of digits, **CInt** to convert the string to type **Integer**, and **ChrW** to convert the number to type **Char**.

```
Dim MyDigits As String   ' Input string of digits to be converted.
Dim CodePoint As Integer   ' Number to be represented as a character.
Dim MyChar As Char
MyDigits = InputBox("Enter code point of character:")
CodePoint = CInt(MyDigits)   ' Convert entire string to Integer.
MyChar = ChrW(CodePoint)   ' MyChar is set to Char value of code point.
```

CDate Example

This example uses the **CDate** function to convert strings to **Date** values. In general, hard-coding dates and times as strings (as shown in this example) is not recommended. Use date literals and time literals, such as #Feb 12, 1969# and #4:45:23 PM#, instead.

```
Dim MyDateString, MyTimeString As String
Dim MyDate, MyTime As Date
MyDateString = "February 12, 1969"
MyTimeString = "4:35:47 PM"
' ...
MyDate = CDate(MyDateString)   ' Convert to Date data type.
MyTime = CDate(MyTimeString)   ' Convert to Date data type.
```

CDbl Example

This example uses the **CDbl** function to convert an expression to **Double**.

```
Dim MyDec As Decimal
Dim MyDouble As Double
MyDec = 234.456784D    ' Literal type character D makes MyDec a Decimal.
MyDouble = CDbl(MyDec * 8.2D * 0.01D)   ' Convert result to a Double.
```

CDec Example

This example uses the **CDec** function to convert a numeric value to **Decimal**.

```
Dim MyDouble As Double
Dim MyDecimal As Decimal
MyDouble = 10000000.0587
MyDecimal = CDec(MyDouble)   ' Convert to Decimal.
```

CInt Example

This example uses the **CInt** function to convert a value to **Integer**.

```
Dim MyDouble As Double
Dim MyInt As Integer
MyDouble = 2345.5678
MyInt = CInt(MyDouble)   ' MyInt is set to 2346.
```

CLng Example

This example uses the **CLng** function to convert values to **Long**.

```
Dim MyDbl1, MyDbl2 As Double
Dim MyLong1, MyLong2 As Long
MyDbl1 = 25427.45
MyDbl2 = 25427.55
MyLong1 = CLng(MyDbl1)   ' MyLong1 contains 25427.
MyLong2 = CLng(MyDbl2)   ' MyLong2 contains 25428.
```

CObj Example

This example uses the **CObj** function to convert a numeric value to **Object**. The **Object** variable itself contains only a four-byte pointer, which points to the **Double** value assigned to it.

```
Dim MyDouble As Double
Dim MyObject As Object
```

```
MyDouble = 2.7182818284
MyObject = CObj(MyDouble)   ' Double value is pointed to by MyObject.
```

CShort Example

This example uses the **CShort** function to convert a numeric value to **Short**.

```
Dim MyByte as Byte
Dim MyShort as Short
MyByte = 100
MyShort = CShort(MyByte)   ' Convert to Short.
```

CSng Example

This example uses the **CSng** function to convert values to **Single**.

```
Dim MyDouble1, MyDouble2 As Double
Dim MySingle1, MySingle2 As Single
MyDouble1 = 75.3421105
MyDouble2 = 75.3421567
MySingle1 = CSng(MyDouble1)   ' MySingle1 is set to 75.34211.
MySingle2 = CSng(MyDouble2)   ' MySingle2 is set to 75.34216.
```

CStr Example

This example uses the **CStr** function to convert a numeric value to **String**.

```
Dim MyDouble As Double
Dim MyString As String
MyDouble = 437.324
MyString = CStr(MyDouble)   ' MyString is set to "437.324".
```

This example uses the **CStr** function to convert **Date** values to **String** values.

```
Dim MyDate As Date
Dim MyString As String
' ...
MyDate = #February 12, 1969 00:00:00#   ' INVALID format.
' Date literals must be in the format #m/d/yyyy# or they are invalid.
' ...
MyDate = #2/12/69 00:00:00#   ' Time is midnight.
' The neutral time value of 00:00:00 is suppressed in the conversion.
MyString = CStr(MyDate)   ' MyString is set to "2/12/1969".
' ...
MyDate = #2/12/69 00:00:01#   ' Time is one second past midnight.
' The time component becomes part of the converted value.
MyString = CStr(MyDate)   ' MyString is set to "2/12/1969 12:00:01 AM".
```

CStr always renders a **Date** value in the standard short format for the current locale, for example, "6/15/2003 4:35:47 PM".

Type Conversion Functions

These functions are compiled inline, meaning the conversion code is part of the code that evaluates the expression. Execution is faster because there is no call to a procedure to accomplish the conversion. Each function coerces an expression to a specific data type.

```
CBool(expression)
CByte(expression)
CChar(expression)
CDate(expression)
CDbl(expression)
CDec(expression)
CInt(expression)
CLng(expression)
CObj(expression)
CShort(expression)
CSng(expression)
CStr(expression)
```

Part

expression
Required. Any **String** expression or numeric expression.

Return Types

The function name determines the return type, as shown in the following table:

Function name	Return type	Range for *expression* argument
CBool	**Boolean**	Any valid **String** or numeric expression.
CByte	**Byte**	0 through 255; fractions are rounded.
CChar	**Char**	Any valid **String** expression; value can be 0 through 65535.
CDate	**Date**	Any valid representation of a date and time.
CDbl	**Double**	-1.79769313486231E+308 through -4.94065645841247E-324 for negative values; 4.94065645841247E-324 through 1.79769313486231E+308 for positive values.
CDec	**Decimal**	+/-79,228,162,514,264,337,593,543,950,335 for zero-scaled numbers, that is, numbers with no decimal places. For numbers with 28 decimal places, the range is +/-7.9228162514264337593543950335. The smallest possible non-zero number is 0.0000000000000000000000000001.
CInt	**Integer**	-2,147,483,648 through 2,147,483,647; fractions are rounded.
CLng	**Long**	-9,223,372,036,854,775,808 through 9,223,372,036,854,775,807; fractions are rounded.
CObj	**Object**	Any valid expression.
CShort	**Short**	-32,768 through 32,767; fractions are rounded.
CSng	**Single**	-3.402823E+38 through -1.401298E-45 for negative values; 1.401298E-45 through 3.402823E+38 for positive values.
CStr	**String**	Returns for **CStr** depend on the *expression* argument. See Returns for CStr.

Remarks

If the *expression* passed to the function is outside the range of the data type to which it is being converted, an error occurs.

In general, you can use the data type conversion functions to force the result of some operation to a particular data type rather than the default data type. For example, use **CDec** to force decimal arithmetic in cases where single-precision, double-precision, or integer arithmetic normally would occur.

When the fractional part is exactly 0.5, **CInt** and **CLng** always round it to the nearest even number. For example, 0.5 rounds to 0

and 1.5 rounds to 2. **CInt** and **CLng** differ from the **Fix** and **Int** functions, which truncate, rather than round, the fractional part of a number. Also, **Fix** and **Int** always return a value of the same type as is passed in.

Use the **IsDate** function to determine if a value can be converted to a date and time. **CDate** recognizes date literals and time literals as well as numbers that fall within the range of acceptable dates.

CDate recognizes date formats according to the locale setting of your system. You must provide the day, month, and year in the correct order for your locale, or the date may not be interpreted correctly. A long date format is not recognized if it contains a day-of-the-week string, such as "Wednesday".

The **Date** data type always contains both date and time information. For purposes of type conversion, Visual Basic .NET considers 1/1/1 (January 1 of the year 1) to be a neutral value for the date, and 00:00:00 (midnight) to be a neutral value for the time. If you convert a **Date** value to a string, **CStr** does not include neutral values in the resulting string. For example, if you convert `#January 1, 0001 9:30:00#` to a string, the result is "9:30:00 AM"; the date information is suppressed. However, the date information is still present in the original **Date** value and can be recovered with functions such as **DatePart**.

The **CType** function takes a second argument, *typename*, and coerces *expression* to *typename*, where *typename* can be any data type, structure, class, or interface. For more information, see CType Function.

CBool Example

This example uses the **CBool** function to convert expressions to **Boolean** values. If an expression evaluates to a nonzero value, **CBool** returns **True**; otherwise, it returns **False**.

```
Dim A, B, C As Integer
Dim Check As Boolean
A = 5
B = 5
Check = CBool(A = B)   ' Check is set to True.
' ...
C = 0
Check = CBool(C)   ' Check is set to False.
```

CByte Example

This example uses the **CByte** function to convert an expression to a **Byte**.

```
Dim MyDouble As Double
Dim MyByte As Byte
MyDouble = 125.5678
MyByte = CByte(MyDouble)   ' MyByte is set to 126.
```

CChar Example

This example uses the **CChar** function to convert a the first character of a **String** expression to a **Char** type.

```
Dim MyString As String
Dim MyChar As Char
MyString = "BCD"   ' CChar converts only first character of string.
MyChar = CChar(MyString)   ' MyChar is set to "B".
```

The input argument to **CChar** must be of data type **String**. You cannot use **CChar** to convert a number to a character, because **CChar** cannot accept a numeric data type. This example obtains a number representing a code point (character code) and converts it to the corresponding character. It uses **InputBox** to obtain the string of digits, **CInt** to convert the string to type **Integer**, and **ChrW** to convert the number to type **Char**.

```
Dim MyDigits As String   ' Input string of digits to be converted.
Dim CodePoint As Integer   ' Number to be represented as a character.
Dim MyChar As Char
MyDigits = InputBox("Enter code point of character:")
CodePoint = CInt(MyDigits)   ' Convert entire string to Integer.
MyChar = ChrW(CodePoint)   ' MyChar is set to Char value of code point.
```

CDate Example

This example uses the **CDate** function to convert strings to **Date** values. In general, hard-coding dates and times as strings (as shown in this example) is not recommended. Use date literals and time literals, such as #Feb 12, 1969# and #4:45:23 PM#, instead.

```
Dim MyDateString, MyTimeString As String
Dim MyDate, MyTime As Date
MyDateString = "February 12, 1969"
MyTimeString = "4:35:47 PM"
' ...
MyDate = CDate(MyDateString)   ' Convert to Date data type.
MyTime = CDate(MyTimeString)   ' Convert to Date data type.
```

CDbl Example

This example uses the **CDbl** function to convert an expression to **Double**.

```
Dim MyDec As Decimal
Dim MyDouble As Double
MyDec = 234.456784D    ' Literal type character D makes MyDec a Decimal.
MyDouble = CDbl(MyDec * 8.2D * 0.01D)   ' Convert result to a Double.
```

CDec Example

This example uses the **CDec** function to convert a numeric value to **Decimal**.

```
Dim MyDouble As Double
Dim MyDecimal As Decimal
MyDouble = 10000000.0587
MyDecimal = CDec(MyDouble)   ' Convert to Decimal.
```

CInt Example

This example uses the **CInt** function to convert a value to **Integer**.

```
Dim MyDouble As Double
Dim MyInt As Integer
MyDouble = 2345.5678
MyInt = CInt(MyDouble)   ' MyInt is set to 2346.
```

CLng Example

This example uses the **CLng** function to convert values to **Long**.

```
Dim MyDbl1, MyDbl2 As Double
Dim MyLong1, MyLong2 As Long
MyDbl1 = 25427.45
MyDbl2 = 25427.55
MyLong1 = CLng(MyDbl1)   ' MyLong1 contains 25427.
MyLong2 = CLng(MyDbl2)   ' MyLong2 contains 25428.
```

CObj Example

This example uses the **CObj** function to convert a numeric value to **Object**. The **Object** variable itself contains only a four-byte pointer, which points to the **Double** value assigned to it.

```
Dim MyDouble As Double
Dim MyObject As Object
```

```
MyDouble = 2.7182818284
MyObject = CObj(MyDouble)   ' Double value is pointed to by MyObject.
```

CShort Example

This example uses the **CShort** function to convert a numeric value to **Short**.

```
Dim MyByte as Byte
Dim MyShort as Short
MyByte = 100
MyShort = CShort(MyByte)   ' Convert to Short.
```

CSng Example

This example uses the **CSng** function to convert values to **Single**.

```
Dim MyDouble1, MyDouble2 As Double
Dim MySingle1, MySingle2 As Single
MyDouble1 = 75.3421105
MyDouble2 = 75.3421567
MySingle1 = CSng(MyDouble1)   ' MySingle1 is set to 75.34211.
MySingle2 = CSng(MyDouble2)   ' MySingle2 is set to 75.34216.
```

CStr Example

This example uses the **CStr** function to convert a numeric value to **String**.

```
Dim MyDouble As Double
Dim MyString As String
MyDouble = 437.324
MyString = CStr(MyDouble)   ' MyString is set to "437.324".
```

This example uses the **CStr** function to convert **Date** values to **String** values.

```
Dim MyDate As Date
Dim MyString As String
' ...
MyDate = #February 12, 1969 00:00:00#   ' INVALID format.
' Date literals must be in the format #m/d/yyyy# or they are invalid.
' ...
MyDate = #2/12/69 00:00:00#   ' Time is midnight.
' The neutral time value of 00:00:00 is suppressed in the conversion.
MyString = CStr(MyDate)   ' MyString is set to "2/12/1969".
' ...
MyDate = #2/12/69 00:00:01#   ' Time is one second past midnight.
' The time component becomes part of the converted value.
MyString = CStr(MyDate)   ' MyString is set to "2/12/1969 12:00:01 AM".
```

CStr always renders a **Date** value in the standard short format for the current locale, for example, "6/15/2003 4:35:47 PM".

Command Function

Returns the argument portion of the command line used to launch Visual Basic or an executable program developed with Visual Basic.

```
Public Function Command() As String
```

Remarks

For applications developed with Visual Basic and compiled to an .exe file, the **Command** function returns any arguments that appear after the name of the application on the command line, as in this example:

```
MyApp cmdlineargs
```

Example

This example uses the **Command** function to return the command-line arguments in an object containing an array.

```
Function GetCommandLineArgs() As String()
   ' Declare variables.
   Dim separators As String = " "
   Dim commands As String = Microsoft.VisualBasic.Command()
   Dim args() As String = commands.Split(separators.ToCharArray)
   Return args
End Function
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Interaction

Assembly: Microsoft.Visual Basic .NET Runtime (in MicrosoftVisualBasic.dll)

Math Functions

The math functions in Visual Basic 6 have been replaced by equivalent methods in the **System.Math** class of the .NET Framework.

Remarks

The .NET Framework math methods are functionally identical to their Visual Basic 6 counterparts, although some have slightly different names. For example, the .NET Framework equivalent of the Visual Basic 6 Atn function is **Atan**. The following table lists the Visual Basic 6 math function names and the equivalent .NET Framework methods.

Visual Basic 6 function	Visual Basic .NET method	Description
Abs	Math.Abs Method	Returns the absolute value of a specified number.
Atn	Math.Atan Method	Returns a **Double** value containing the angle whose tangent is the specified number.
Cos	Math.Cos Method	Returns a **Double** value containing the cosine of the specified angle.
Exp	Math.Exp Method	Returns a **Double** value containing e (the base of natural logarithms) raised to the specified power.
Log	Math.Log Method	Returns a **Double** value containing the logarithm of a specified number. This method is overloaded and can return either the natural (base e) logarithm of a specified number or the logarithm of a specified number in a specified base.
Round	Math.Round Method	Returns a **Double** value containing the number nearest the specified value. Additional round functions are available as methods of the intrinsic types such as Decimal.Round Method.
Sgn	Math.Sign Method	Returns an **Integer** value indicating the sign of a number.
Sin	Math.Sin Method	Returns a **Double** value specifying the sine of an angle.
Sqr	Math.Sqrt Method	Returns a **Double** value specifying the square root of a number.
Tan	Math.Tan Method	Returns a **Double** value containing the tangent of an angle.

In addition, the .NET Framework math class provides constants and other static methods for trigonometric, logarithmic, and other common mathematical functions. All of these can be used in a Visual Basic program.

To use these functions without qualification, import the **System.Math** namespace into your project by adding the following code to the top of the source code:

```
Imports System.Math
```

Requirements

Class: Math Class

Abs Example

This example uses the **Abs** method of the **Math** class to compute the absolute value of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyNumber As Double
```

```
MyNumber = Abs(50.3)    ' Returns 50.3.
MyNumber = Abs(-50.3)   ' Returns 50.3.
```

Atan Example

This example uses the **Atan** method of the **Math** class to calculate the value of pi.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim pi As Double
pi = 4 * Atan(1)   ' Calculate the value of pi.
```

Cos Example

This example uses the **Cos** method of the **Math** class to return the cosine of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MySecant As Double
MyAngle = 1.3   ' Define angle in radians.
MySecant = 1 / Cos(MyAngle)   ' Calculate secant.
```

Exp Example

This example uses the **Exp** method of the **Math** class to return *e* raised to a power.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyHSin As Double
' Define angle in radians.
MyAngle = 1.3
' Calculate hyperbolic sine.
MyHSin = (Exp(MyAngle) - Exp(-1 * MyAngle)) / 2
```

Log Example

This example uses the **Log** method of the **Math** class to return the natural logarithm of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyLog As Double
' Define angle in radians.
MyAngle = 1.3
' Calculate inverse hyperbolic sine.
MyLog = Log(MyAngle + Sqrt(MyAngle * MyAngle + 1))
```

Round Example

This example uses the **Round** method of the **Math** class to round a number to the nearest integer.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyVar1 As Double = 2.8
Dim MyVar2 As Double
MyVar2 =Round(MyVar1)   ' Returns 3.
```

Sign Example

This example uses the **Sign** method of the **Math** class to determine the sign of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyVar1, MyVar2, MyVar3 As Double
Dim MySign As Integer
MyVar1 = 12
MyVar2 = -2.4
MyVar3 = 0
MySign = Sign(MyVar1)   ' Returns 1.
MySign = Sign(MyVar2)   ' Returns -1.
MySign = Sign(MyVar3)   ' Returns 0.
```

Sin Example

This example uses the **Sin** method of the **Math** class to return the sine of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyCosecant As Double
MyAngle = 1.3   ' Define angle in radians.
MyCosecant = 1 / Sin(MyAngle)   ' Calculate cosecant.
```

Sqrt Example

This example uses the **Sqrt** method of the **Math** class to calculate the square root of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MySqr As Double
MySqr = Sqrt(4)    ' Returns 2.
MySqr = Sqrt(23)   ' Returns 4.79583152331272.
MySqr = Sqrt(0)    ' Returns 0.
MySqr = Sqrt(-4)   ' Returns NaN (not a number).
```

Tan Example

This example uses the **Tan** method of the **Math** class to return the tangent of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyCotangent As Double
MyAngle = 1.3   ' Define angle in radians.
MyCotangent = 1 / Tan(MyAngle)   ' Calculate cotangent.
```

Requirements

Namespace: System.Math

Assembly: mscorlib (in mscorlib.dll)

See Also

Rnd Function | Randomize Statement | Derived Math Functions | Double.NaN Field

CreateObject Function

Creates and returns a reference to a COM object. **CreateObject** cannot be used to create instances of classes in Visual Basic unless those classes are explicitly exposed as COM components.

```
Public Shared Function CreateObject( _
   ByVal ProgId As String, _
   Optional ByVal ServerName As String = "" _
) As Object
```

Parameters

ProgId
Required. **String**. The program ID of the object to create.
ServerName
Optional. **String**. The name of the network server where the object will be created. If *ServerName* is an empty string (""), the local machine is used.

Exceptions/Errors

Exception type	Error number	Condition
Exception	429	*ProgId* not found or not supplied.
Exception	462	Server is unavailable
FileNotFoundException	53	No object of the specified type exists .

Remarks

To create an instance of a COM component, assign the object returned by **CreateObject** to an object variable:

```
Sub CreateADODB()
   Dim adoApp As Object
   adoApp = CreateObject("ADODB.Connection")
End Sub
```

The type of object variable you use to store the returned object can affect your application's performance. Declaring an object variable with the **As Object** clause creates a variable that can contain a reference to any type of object. However, access to the object through that variable is late bound; that is, the binding occurs when your program is run. There are many reasons you should avoid late binding, including slower application performance. To create an object variable that results in early binding, that is, binding when the program is compiled, add a reference to the type library for your object from the **COM** tab of the **Add Reference** dialog box on the **Project** menu and declare the object variable of the specific type of your object. In most cases, it is more efficient to use the **Dim** statement and a primary interop assembly to create objects than it is to use the **CreateObject** function.

Another issue is that COM objects use unmanaged code — code without the benefit of the common language runtime. There is a fair degree of complexity involved in mixing the managed code of Visual Basic .NET with unmanaged code from COM. When you add a reference to a COM object, a search is made for a Primary Interop Assembly for that library; if one is found then it is used. If none is found Visual Basic .NET creates an interoperability assembly that contains local interoperability classes for each class in the COM library. For more information, see COM Interoperability in Visual Basic and Visual C#. You should generally use strongly bound objects and primary interop assemblies whenever possible. The examples below use the **CreateObject** function with Microsoft Office objects for demonstration purposes only. However, these objects are easier to use and more reliable when used with the appropriate primary interop assembly.

You can create an object on a remote networked computer by passing the name of the computer to the *ServerName* argument of the **CreateObject** function. That name is the same as the Machine Name portion of a share name: for a share named "\\MyServer\Public," *ServerName* is "MyServer."

> **Note** Refer to COM documentation (see Microsoft Developer Network) for additional information on making an application accessible on a remote networked computer. You may need to add a registry key for your application.

The following code returns the version number of an instance of Excel running on a remote computer named `MyServer`:

```
Sub CreateRemoteExcelObj()
   Dim xlApp As Object
   ' Replace string "\\MyServer" with name of the remote computer.
   xlApp = CreateObject("Excel.Application", "\\MyServer")
   MsgBox(xlApp.Version)
End Sub
```

If the remote server name is incorrect, or if it is unavailable, a run-time error occurs.

> **Note** Use **CreateObject** when there is no current instance of the object. If an instance of the object is already running, a new instance is started, and an object of the specified type is created. To use the current instance, or to start the application and have it load a file, use the **GetObject** function. If an object has registered itself as a single-instance object, only one instance of the object is created, no matter how many times **CreateObject** is executed.

Example

This example uses the **CreateObject** function to create a Microsoft Excel worksheet and saves the worksheet to a file. To use this example, Excel must be installed on the computer where this program will run, and you must add a reference to the type library from the **COM** tab of the **Add Reference** dialog box on the **Project** menu. The name of the type library will vary depending on the version of Excel installed on your computer. For example, the type library for Microsoft Excel 2002 is named **Microsoft Excel 10.0 Object Library**.

```
Sub TestExcel()
   Dim xlApp As Excel.Application
   Dim xlBook As Excel.Workbook
   Dim xlSheet As Excel.Worksheet
   xlApp = CType(CreateObject("Excel.Application"), Excel.Application)
   xlBook = CType(xlApp.Workbooks.Add, Excel.Workbook)
   xlSheet = CType(xlBook.Worksheets(1), Excel.Worksheet)
   ' Place some text in the second row of the sheet.
   xlSheet.Cells(2, 2) = "This is column B row 2"
   ' Show the sheet.
   xlSheet.Application.Visible = True
   ' Save the sheet to C:\Test.xls directory.
   xlSheet.SaveAs("C:\Test.xls")
   ' Optionally, you can call xlApp.Quit to close the work sheet.
End Sub
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: Interaction

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Type Conversion Functions

These functions are compiled inline, meaning the conversion code is part of the code that evaluates the expression. Execution is faster because there is no call to a procedure to accomplish the conversion. Each function coerces an expression to a specific data type.

```
CBool(expression)
CByte(expression)
CChar(expression)
CDate(expression)
CDbl(expression)
CDec(expression)
CInt(expression)
CLng(expression)
CObj(expression)
CShort(expression)
CSng(expression)
CStr(expression)
```

Part

expression
Required. Any **String** expression or numeric expression.

Return Types

The function name determines the return type, as shown in the following table:

Function name	Return type	Range for *expression* argument
CBool	**Boolean**	Any valid **String** or numeric expression.
CByte	**Byte**	0 through 255; fractions are rounded.
CChar	**Char**	Any valid **String** expression; value can be 0 through 65535.
CDate	**Date**	Any valid representation of a date and time.
CDbl	**Double**	-1.79769313486231E+308 through -4.94065645841247E-324 for negative values; 4.94065645841247E-324 through 1.79769313486231E+308 for positive values.
CDec	**Decimal**	+/-79,228,162,514,264,337,593,543,950,335 for zero-scaled numbers, that is, numbers with no decimal places. For numbers with 28 decimal places, the range is +/-7.9228162514264337593543950335. The smallest possible non-zero number is 0.0000000000000000000000000001.
CInt	**Integer**	-2,147,483,648 through 2,147,483,647; fractions are rounded.
CLng	**Long**	-9,223,372,036,854,775,808 through 9,223,372,036,854,775,807; fractions are rounded.
CObj	**Object**	Any valid expression.
CShort	**Short**	-32,768 through 32,767; fractions are rounded.
CSng	**Single**	-3.402823E+38 through -1.401298E-45 for negative values; 1.401298E-45 through 3.402823E+38 for positive values.
CStr	**String**	Returns for **CStr** depend on the *expression* argument. See Returns for CStr.

Remarks

If the *expression* passed to the function is outside the range of the data type to which it is being converted, an error occurs.

In general, you can use the data type conversion functions to force the result of some operation to a particular data type rather than the default data type. For example, use **CDec** to force decimal arithmetic in cases where single-precision, double-precision, or integer arithmetic normally would occur.

When the fractional part is exactly 0.5, **CInt** and **CLng** always round it to the nearest even number. For example, 0.5 rounds to 0

and 1.5 rounds to 2. **CInt** and **CLng** differ from the **Fix** and **Int** functions, which truncate, rather than round, the fractional part of a number. Also, **Fix** and **Int** always return a value of the same type as is passed in.

Use the **IsDate** function to determine if a value can be converted to a date and time. **CDate** recognizes date literals and time literals as well as numbers that fall within the range of acceptable dates.

CDate recognizes date formats according to the locale setting of your system. You must provide the day, month, and year in the correct order for your locale, or the date may not be interpreted correctly. A long date format is not recognized if it contains a day-of-the-week string, such as "Wednesday".

The **Date** data type always contains both date and time information. For purposes of type conversion, Visual Basic .NET considers 1/1/1 (January 1 of the year 1) to be a neutral value for the date, and 00:00:00 (midnight) to be a neutral value for the time. If you convert a **Date** value to a string, **CStr** does not include neutral values in the resulting string. For example, if you convert `#January 1, 0001 9:30:00#` to a string, the result is "9:30:00 AM"; the date information is suppressed. However, the date information is still present in the original **Date** value and can be recovered with functions such as **DatePart**.

The **CType** function takes a second argument, *typename*, and coerces *expression* to *typename*, where *typename* can be any data type, structure, class, or interface. For more information, see CType Function.

CBool Example

This example uses the **CBool** function to convert expressions to **Boolean** values. If an expression evaluates to a nonzero value, **CBool** returns **True**; otherwise, it returns **False**.

```
Dim A, B, C As Integer
Dim Check As Boolean
A = 5
B = 5
Check = CBool(A = B)   ' Check is set to True.
' ...
C = 0
Check = CBool(C)   ' Check is set to False.
```

CByte Example

This example uses the **CByte** function to convert an expression to a **Byte**.

```
Dim MyDouble As Double
Dim MyByte As Byte
MyDouble = 125.5678
MyByte = CByte(MyDouble)   ' MyByte is set to 126.
```

CChar Example

This example uses the **CChar** function to convert a the first character of a **String** expression to a **Char** type.

```
Dim MyString As String
Dim MyChar As Char
MyString = "BCD"   ' CChar converts only first character of string.
MyChar = CChar(MyString)   ' MyChar is set to "B".
```

The input argument to **CChar** must be of data type **String**. You cannot use **CChar** to convert a number to a character, because **CChar** cannot accept a numeric data type. This example obtains a number representing a code point (character code) and converts it to the corresponding character. It uses **InputBox** to obtain the string of digits, **CInt** to convert the string to type **Integer**, and **ChrW** to convert the number to type **Char**.

```
Dim MyDigits As String   ' Input string of digits to be converted.
Dim CodePoint As Integer   ' Number to be represented as a character.
Dim MyChar As Char
MyDigits = InputBox("Enter code point of character:")
CodePoint = CInt(MyDigits)   ' Convert entire string to Integer.
MyChar = ChrW(CodePoint)   ' MyChar is set to Char value of code point.
```

CDate Example

This example uses the **CDate** function to convert strings to **Date** values. In general, hard-coding dates and times as strings (as shown in this example) is not recommended. Use date literals and time literals, such as #Feb 12, 1969# and #4:45:23 PM#, instead.

```
Dim MyDateString, MyTimeString As String
Dim MyDate, MyTime As Date
MyDateString = "February 12, 1969"
MyTimeString = "4:35:47 PM"
' ...
MyDate = CDate(MyDateString)   ' Convert to Date data type.
MyTime = CDate(MyTimeString)   ' Convert to Date data type.
```

CDbl Example

This example uses the **CDbl** function to convert an expression to **Double**.

```
Dim MyDec As Decimal
Dim MyDouble As Double
MyDec = 234.456784D    ' Literal type character D makes MyDec a Decimal.
MyDouble = CDbl(MyDec * 8.2D * 0.01D)   ' Convert result to a Double.
```

CDec Example

This example uses the **CDec** function to convert a numeric value to **Decimal**.

```
Dim MyDouble As Double
Dim MyDecimal As Decimal
MyDouble = 10000000.0587
MyDecimal = CDec(MyDouble)   ' Convert to Decimal.
```

CInt Example

This example uses the **CInt** function to convert a value to **Integer**.

```
Dim MyDouble As Double
Dim MyInt As Integer
MyDouble = 2345.5678
MyInt = CInt(MyDouble)   ' MyInt is set to 2346.
```

CLng Example

This example uses the **CLng** function to convert values to **Long**.

```
Dim MyDbl1, MyDbl2 As Double
Dim MyLong1, MyLong2 As Long
MyDbl1 = 25427.45
MyDbl2 = 25427.55
MyLong1 = CLng(MyDbl1)   ' MyLong1 contains 25427.
MyLong2 = CLng(MyDbl2)   ' MyLong2 contains 25428.
```

CObj Example

This example uses the **CObj** function to convert a numeric value to **Object**. The **Object** variable itself contains only a four-byte pointer, which points to the **Double** value assigned to it.

```
Dim MyDouble As Double
Dim MyObject As Object
```

```
MyDouble = 2.7182818284
MyObject = CObj(MyDouble)   ' Double value is pointed to by MyObject.
```

CShort Example

This example uses the **CShort** function to convert a numeric value to **Short**.

```
Dim MyByte as Byte
Dim MyShort as Short
MyByte = 100
MyShort = CShort(MyByte)   ' Convert to Short.
```

CSng Example

This example uses the **CSng** function to convert values to **Single**.

```
Dim MyDouble1, MyDouble2 As Double
Dim MySingle1, MySingle2 As Single
MyDouble1 = 75.3421105
MyDouble2 = 75.3421567
MySingle1 = CSng(MyDouble1)   ' MySingle1 is set to 75.34211.
MySingle2 = CSng(MyDouble2)   ' MySingle2 is set to 75.34216.
```

CStr Example

This example uses the **CStr** function to convert a numeric value to **String**.

```
Dim MyDouble As Double
Dim MyString As String
MyDouble = 437.324
MyString = CStr(MyDouble)   ' MyString is set to "437.324".
```

This example uses the **CStr** function to convert **Date** values to **String** values.

```
Dim MyDate As Date
Dim MyString As String
' ...
MyDate = #February 12, 1969 00:00:00#   ' INVALID format.
' Date literals must be in the format #m/d/yyyy# or they are invalid.
' ...
MyDate = #2/12/69 00:00:00#   ' Time is midnight.
' The neutral time value of 00:00:00 is suppressed in the conversion.
MyString = CStr(MyDate)   ' MyString is set to "2/12/1969".
' ...
MyDate = #2/12/69 00:00:01#   ' Time is one second past midnight.
' The time component becomes part of the converted value.
MyString = CStr(MyDate)   ' MyString is set to "2/12/1969 12:00:01 AM".
```

CStr always renders a **Date** value in the standard short format for the current locale, for example, "6/15/2003 4:35:47 PM".

Type Conversion Functions

These functions are compiled inline, meaning the conversion code is part of the code that evaluates the expression. Execution is faster because there is no call to a procedure to accomplish the conversion. Each function coerces an expression to a specific data type.

```
CBool(expression)
CByte(expression)
CChar(expression)
CDate(expression)
CDbl(expression)
CDec(expression)
CInt(expression)
CLng(expression)
CObj(expression)
CShort(expression)
CSng(expression)
CStr(expression)
```

Part

expression
Required. Any **String** expression or numeric expression.

Return Types

The function name determines the return type, as shown in the following table:

Function name	Return type	Range for *expression* argument
CBool	**Boolean**	Any valid **String** or numeric expression.
CByte	**Byte**	0 through 255; fractions are rounded.
CChar	**Char**	Any valid **String** expression; value can be 0 through 65535.
CDate	**Date**	Any valid representation of a date and time.
CDbl	**Double**	-1.79769313486231E+308 through -4.94065645841247E-324 for negative values; 4.94065645841247E-324 through 1.79769313486231E+308 for positive values.
CDec	**Decimal**	+/-79,228,162,514,264,337,593,543,950,335 for zero-scaled numbers, that is, numbers with no decimal places. For numbers with 28 decimal places, the range is +/-7.9228162514264337593543950335. The smallest possible non-zero number is 0.0000000000000000000000000001.
CInt	**Integer**	-2,147,483,648 through 2,147,483,647; fractions are rounded.
CLng	**Long**	-9,223,372,036,854,775,808 through 9,223,372,036,854,775,807; fractions are rounded.
CObj	**Object**	Any valid expression.
CShort	**Short**	-32,768 through 32,767; fractions are rounded.
CSng	**Single**	-3.402823E+38 through -1.401298E-45 for negative values; 1.401298E-45 through 3.402823E+38 for positive values.
CStr	**String**	Returns for **CStr** depend on the *expression* argument. See Returns for CStr.

Remarks

If the *expression* passed to the function is outside the range of the data type to which it is being converted, an error occurs.

In general, you can use the data type conversion functions to force the result of some operation to a particular data type rather than the default data type. For example, use **CDec** to force decimal arithmetic in cases where single-precision, double-precision, or integer arithmetic normally would occur.

When the fractional part is exactly 0.5, **CInt** and **CLng** always round it to the nearest even number. For example, 0.5 rounds to 0

and 1.5 rounds to 2. **CInt** and **CLng** differ from the **Fix** and **Int** functions, which truncate, rather than round, the fractional part of a number. Also, **Fix** and **Int** always return a value of the same type as is passed in.

Use the **IsDate** function to determine if a value can be converted to a date and time. **CDate** recognizes date literals and time literals as well as numbers that fall within the range of acceptable dates.

CDate recognizes date formats according to the locale setting of your system. You must provide the day, month, and year in the correct order for your locale, or the date may not be interpreted correctly. A long date format is not recognized if it contains a day-of-the-week string, such as "Wednesday".

The **Date** data type always contains both date and time information. For purposes of type conversion, Visual Basic .NET considers 1/1/1 (January 1 of the year 1) to be a neutral value for the date, and 00:00:00 (midnight) to be a neutral value for the time. If you convert a **Date** value to a string, **CStr** does not include neutral values in the resulting string. For example, if you convert `#January 1, 0001 9:30:00#` to a string, the result is "9:30:00 AM"; the date information is suppressed. However, the date information is still present in the original **Date** value and can be recovered with functions such as **DatePart**.

The **CType** function takes a second argument, *typename*, and coerces *expression* to *typename*, where *typename* can be any data type, structure, class, or interface. For more information, see CType Function.

CBool Example

This example uses the **CBool** function to convert expressions to **Boolean** values. If an expression evaluates to a nonzero value, **CBool** returns **True**; otherwise, it returns **False**.

```
Dim A, B, C As Integer
Dim Check As Boolean
A = 5
B = 5
Check = CBool(A = B)   ' Check is set to True.
' ...
C = 0
Check = CBool(C)   ' Check is set to False.
```

CByte Example

This example uses the **CByte** function to convert an expression to a **Byte**.

```
Dim MyDouble As Double
Dim MyByte As Byte
MyDouble = 125.5678
MyByte = CByte(MyDouble)   ' MyByte is set to 126.
```

CChar Example

This example uses the **CChar** function to convert a the first character of a **String** expression to a **Char** type.

```
Dim MyString As String
Dim MyChar As Char
MyString = "BCD"   ' CChar converts only first character of string.
MyChar = CChar(MyString)   ' MyChar is set to "B".
```

The input argument to **CChar** must be of data type **String**. You cannot use **CChar** to convert a number to a character, because **CChar** cannot accept a numeric data type. This example obtains a number representing a code point (character code) and converts it to the corresponding character. It uses **InputBox** to obtain the string of digits, **CInt** to convert the string to type **Integer**, and **ChrW** to convert the number to type **Char**.

```
Dim MyDigits As String   ' Input string of digits to be converted.
Dim CodePoint As Integer   ' Number to be represented as a character.
Dim MyChar As Char
MyDigits = InputBox("Enter code point of character:")
CodePoint = CInt(MyDigits)   ' Convert entire string to Integer.
MyChar = ChrW(CodePoint)   ' MyChar is set to Char value of code point.
```

CDate Example

This example uses the **CDate** function to convert strings to **Date** values. In general, hard-coding dates and times as strings (as shown in this example) is not recommended. Use date literals and time literals, such as #Feb 12, 1969# and #4:45:23 PM#, instead.

```
Dim MyDateString, MyTimeString As String
Dim MyDate, MyTime As Date
MyDateString = "February 12, 1969"
MyTimeString = "4:35:47 PM"
' ...
MyDate = CDate(MyDateString)   ' Convert to Date data type.
MyTime = CDate(MyTimeString)   ' Convert to Date data type.
```

CDbl Example

This example uses the **CDbl** function to convert an expression to **Double**.

```
Dim MyDec As Decimal
Dim MyDouble As Double
MyDec = 234.456784D    ' Literal type character D makes MyDec a Decimal.
MyDouble = CDbl(MyDec * 8.2D * 0.01D)   ' Convert result to a Double.
```

CDec Example

This example uses the **CDec** function to convert a numeric value to **Decimal**.

```
Dim MyDouble As Double
Dim MyDecimal As Decimal
MyDouble = 10000000.0587
MyDecimal = CDec(MyDouble)   ' Convert to Decimal.
```

CInt Example

This example uses the **CInt** function to convert a value to **Integer**.

```
Dim MyDouble As Double
Dim MyInt As Integer
MyDouble = 2345.5678
MyInt = CInt(MyDouble)   ' MyInt is set to 2346.
```

CLng Example

This example uses the **CLng** function to convert values to **Long**.

```
Dim MyDbl1, MyDbl2 As Double
Dim MyLong1, MyLong2 As Long
MyDbl1 = 25427.45
MyDbl2 = 25427.55
MyLong1 = CLng(MyDbl1)   ' MyLong1 contains 25427.
MyLong2 = CLng(MyDbl2)   ' MyLong2 contains 25428.
```

CObj Example

This example uses the **CObj** function to convert a numeric value to **Object**. The **Object** variable itself contains only a four-byte pointer, which points to the **Double** value assigned to it.

```
Dim MyDouble As Double
Dim MyObject As Object
```

```
MyDouble = 2.7182818284
MyObject = CObj(MyDouble)   ' Double value is pointed to by MyObject.
```

CShort Example

This example uses the **CShort** function to convert a numeric value to **Short**.

```
Dim MyByte as Byte
Dim MyShort as Short
MyByte = 100
MyShort = CShort(MyByte)   ' Convert to Short.
```

CSng Example

This example uses the **CSng** function to convert values to **Single**.

```
Dim MyDouble1, MyDouble2 As Double
Dim MySingle1, MySingle2 As Single
MyDouble1 = 75.3421105
MyDouble2 = 75.3421567
MySingle1 = CSng(MyDouble1)   ' MySingle1 is set to 75.34211.
MySingle2 = CSng(MyDouble2)   ' MySingle2 is set to 75.34216.
```

CStr Example

This example uses the **CStr** function to convert a numeric value to **String**.

```
Dim MyDouble As Double
Dim MyString As String
MyDouble = 437.324
MyString = CStr(MyDouble)   ' MyString is set to "437.324".
```

This example uses the **CStr** function to convert **Date** values to **String** values.

```
Dim MyDate As Date
Dim MyString As String
' ...
MyDate = #February 12, 1969 00:00:00#   ' INVALID format.
' Date literals must be in the format #m/d/yyyy# or they are invalid.
' ...
MyDate = #2/12/69 00:00:00#   ' Time is midnight.
' The neutral time value of 00:00:00 is suppressed in the conversion.
MyString = CStr(MyDate)   ' MyString is set to "2/12/1969".
' ...
MyDate = #2/12/69 00:00:01#   ' Time is one second past midnight.
' The time component becomes part of the converted value.
MyString = CStr(MyDate)   ' MyString is set to "2/12/1969 12:00:01 AM".
```

CStr always renders a **Date** value in the standard short format for the current locale, for example, "6/15/2003 4:35:47 PM".

Conversion Functions | CType Function | Asc, AscW Functions | Chr, ChrW Functions | Format Function | Hex Function | Oct Function | Str Function | Val Function | DatePart Function | Returns for CStr | Type Conversions

Type Conversion Functions

These functions are compiled inline, meaning the conversion code is part of the code that evaluates the expression. Execution is faster because there is no call to a procedure to accomplish the conversion. Each function coerces an expression to a specific data type.

```
CBool(expression)
CByte(expression)
CChar(expression)
CDate(expression)
CDbl(expression)
CDec(expression)
CInt(expression)
CLng(expression)
CObj(expression)
CShort(expression)
CSng(expression)
CStr(expression)
```

Part

expression
Required. Any **String** expression or numeric expression.

Return Types

The function name determines the return type, as shown in the following table:

Function name	Return type	Range for *expression* argument
CBool	**Boolean**	Any valid **String** or numeric expression.
CByte	**Byte**	0 through 255; fractions are rounded.
CChar	**Char**	Any valid **String** expression; value can be 0 through 65535.
CDate	**Date**	Any valid representation of a date and time.
CDbl	**Double**	-1.79769313486231E+308 through -4.94065645841247E-324 for negative values; 4.94065645841247E-324 through 1.79769313486231E+308 for positive values.
CDec	**Decimal**	+/-79,228,162,514,264,337,593,543,950,335 for zero-scaled numbers, that is, numbers with no decimal places. For numbers with 28 decimal places, the range is +/-7.9228162514264337593543950335. The smallest possible non-zero number is 0.0000000000000000000000000001.
CInt	**Integer**	-2,147,483,648 through 2,147,483,647; fractions are rounded.
CLng	**Long**	-9,223,372,036,854,775,808 through 9,223,372,036,854,775,807; fractions are rounded.
CObj	**Object**	Any valid expression.
CShort	**Short**	-32,768 through 32,767; fractions are rounded.
CSng	**Single**	-3.402823E+38 through -1.401298E-45 for negative values; 1.401298E-45 through 3.402823E+38 for positive values.
CStr	**String**	Returns for **CStr** depend on the *expression* argument. See Returns for CStr.

Remarks

If the *expression* passed to the function is outside the range of the data type to which it is being converted, an error occurs.

In general, you can use the data type conversion functions to force the result of some operation to a particular data type rather than the default data type. For example, use **CDec** to force decimal arithmetic in cases where single-precision, double-precision, or integer arithmetic normally would occur.

When the fractional part is exactly 0.5, **CInt** and **CLng** always round it to the nearest even number. For example, 0.5 rounds to 0

and 1.5 rounds to 2. **CInt** and **CLng** differ from the **Fix** and **Int** functions, which truncate, rather than round, the fractional part of a number. Also, **Fix** and **Int** always return a value of the same type as is passed in.

Use the **IsDate** function to determine if a value can be converted to a date and time. **CDate** recognizes date literals and time literals as well as numbers that fall within the range of acceptable dates.

CDate recognizes date formats according to the locale setting of your system. You must provide the day, month, and year in the correct order for your locale, or the date may not be interpreted correctly. A long date format is not recognized if it contains a day-of-the-week string, such as "Wednesday".

The **Date** data type always contains both date and time information. For purposes of type conversion, Visual Basic .NET considers 1/1/1 (January 1 of the year 1) to be a neutral value for the date, and 00:00:00 (midnight) to be a neutral value for the time. If you convert a **Date** value to a string, **CStr** does not include neutral values in the resulting string. For example, if you convert `#January 1, 0001 9:30:00#` to a string, the result is "9:30:00 AM"; the date information is suppressed. However, the date information is still present in the original **Date** value and can be recovered with functions such as **DatePart**.

The **CType** function takes a second argument, *typename*, and coerces *expression* to *typename*, where *typename* can be any data type, structure, class, or interface. For more information, see CType Function.

CBool Example

This example uses the **CBool** function to convert expressions to **Boolean** values. If an expression evaluates to a nonzero value, **CBool** returns **True**; otherwise, it returns **False**.

```
Dim A, B, C As Integer
Dim Check As Boolean
A = 5
B = 5
Check = CBool(A = B)   ' Check is set to True.
' ...
C = 0
Check = CBool(C)   ' Check is set to False.
```

CByte Example

This example uses the **CByte** function to convert an expression to a **Byte**.

```
Dim MyDouble As Double
Dim MyByte As Byte
MyDouble = 125.5678
MyByte = CByte(MyDouble)   ' MyByte is set to 126.
```

CChar Example

This example uses the **CChar** function to convert a the first character of a **String** expression to a **Char** type.

```
Dim MyString As String
Dim MyChar As Char
MyString = "BCD"   ' CChar converts only first character of string.
MyChar = CChar(MyString)   ' MyChar is set to "B".
```

The input argument to **CChar** must be of data type **String**. You cannot use **CChar** to convert a number to a character, because **CChar** cannot accept a numeric data type. This example obtains a number representing a code point (character code) and converts it to the corresponding character. It uses **InputBox** to obtain the string of digits, **CInt** to convert the string to type **Integer**, and **ChrW** to convert the number to type **Char**.

```
Dim MyDigits As String   ' Input string of digits to be converted.
Dim CodePoint As Integer   ' Number to be represented as a character.
Dim MyChar As Char
MyDigits = InputBox("Enter code point of character:")
CodePoint = CInt(MyDigits)   ' Convert entire string to Integer.
MyChar = ChrW(CodePoint)   ' MyChar is set to Char value of code point.
```

CDate Example

This example uses the **CDate** function to convert strings to **Date** values. In general, hard-coding dates and times as strings (as shown in this example) is not recommended. Use date literals and time literals, such as #Feb 12, 1969# and #4:45:23 PM#, instead.

```
Dim MyDateString, MyTimeString As String
Dim MyDate, MyTime As Date
MyDateString = "February 12, 1969"
MyTimeString = "4:35:47 PM"
' ...
MyDate = CDate(MyDateString)   ' Convert to Date data type.
MyTime = CDate(MyTimeString)   ' Convert to Date data type.
```

CDbl Example

This example uses the **CDbl** function to convert an expression to **Double**.

```
Dim MyDec As Decimal
Dim MyDouble As Double
MyDec = 234.456784D    ' Literal type character D makes MyDec a Decimal.
MyDouble = CDbl(MyDec * 8.2D * 0.01D)   ' Convert result to a Double.
```

CDec Example

This example uses the **CDec** function to convert a numeric value to **Decimal**.

```
Dim MyDouble As Double
Dim MyDecimal As Decimal
MyDouble = 10000000.0587
MyDecimal = CDec(MyDouble)   ' Convert to Decimal.
```

CInt Example

This example uses the **CInt** function to convert a value to **Integer**.

```
Dim MyDouble As Double
Dim MyInt As Integer
MyDouble = 2345.5678
MyInt = CInt(MyDouble)   ' MyInt is set to 2346.
```

CLng Example

This example uses the **CLng** function to convert values to **Long**.

```
Dim MyDbl1, MyDbl2 As Double
Dim MyLong1, MyLong2 As Long
MyDbl1 = 25427.45
MyDbl2 = 25427.55
MyLong1 = CLng(MyDbl1)   ' MyLong1 contains 25427.
MyLong2 = CLng(MyDbl2)   ' MyLong2 contains 25428.
```

CObj Example

This example uses the **CObj** function to convert a numeric value to **Object**. The **Object** variable itself contains only a four-byte pointer, which points to the **Double** value assigned to it.

```
Dim MyDouble As Double
Dim MyObject As Object
```

```
MyDouble = 2.7182818284
MyObject = CObj(MyDouble)   ' Double value is pointed to by MyObject.
```

CShort Example

This example uses the **CShort** function to convert a numeric value to **Short**.

```
Dim MyByte as Byte
Dim MyShort as Short
MyByte = 100
MyShort = CShort(MyByte)   ' Convert to Short.
```

CSng Example

This example uses the **CSng** function to convert values to **Single**.

```
Dim MyDouble1, MyDouble2 As Double
Dim MySingle1, MySingle2 As Single
MyDouble1 = 75.3421105
MyDouble2 = 75.3421567
MySingle1 = CSng(MyDouble1)   ' MySingle1 is set to 75.34211.
MySingle2 = CSng(MyDouble2)   ' MySingle2 is set to 75.34216.
```

CStr Example

This example uses the **CStr** function to convert a numeric value to **String**.

```
Dim MyDouble As Double
Dim MyString As String
MyDouble = 437.324
MyString = CStr(MyDouble)   ' MyString is set to "437.324".
```

This example uses the **CStr** function to convert **Date** values to **String** values.

```
Dim MyDate As Date
Dim MyString As String
' ...
MyDate = #February 12, 1969 00:00:00#   ' INVALID format.
' Date literals must be in the format #m/d/yyyy# or they are invalid.
' ...
MyDate = #2/12/69 00:00:00#   ' Time is midnight.
' The neutral time value of 00:00:00 is suppressed in the conversion.
MyString = CStr(MyDate)   ' MyString is set to "2/12/1969".
' ...
MyDate = #2/12/69 00:00:01#   ' Time is one second past midnight.
' The time component becomes part of the converted value.
MyString = CStr(MyDate)   ' MyString is set to "2/12/1969 12:00:01 AM".
```

CStr always renders a **Date** value in the standard short format for the current locale, for example, "6/15/2003 4:35:47 PM".

Conversion Functions | CType Function | Asc, AscW Functions | Chr, ChrW Functions | Format Function | Hex Function | Oct Function | Str Function | Val Function | DatePart Function | Returns for CStr | Type Conversions

CType Function

Returns the result of explicitly converting an expression to a specified data type, object, structure, class, or interface.

```
CType(expression, typename)
```

Parts

expression
Any valid expression. If the value of *expression* is outside the range allowed by *typename*, an error occurs.

typename
Any expression that is legal within an **As** clause in a **Dim** statement, that is, the name of any data type, object, structure, class, or interface.

Remarks

CType is compiled inline, meaning the conversion code is part of the code that evaluates the expression. Execution is faster because there is no call to a procedure to accomplish the conversion.

Example

This example uses the **CType** function to convert an expression to the specified data type.

```
Dim MyNumber As Long
Dim MyNewType As Single
MyNumber = 1000
MyNewType = CType(MyNumber,Single)   ' MyNewType is set to 1000.0.
```

Type Conversion Functions

CurDir Function

Returns a string representing the current path.

```
Public Overloads Function CurDir([ ByVal Drive As Char ]) As String
```

Parameter

Drive
Optional. **Char** expression that specifies an existing drive. If no drive is specified, or if *Drive* is a zero-length string (""), **CurDir** returns the path for the current drive.

Exceptions/Errors

Exception type	Error number	Condition
IOException	68	*Drive* is not found.
ArgumentException	68	Invalid *Drive* is specified.

Example

This example uses the **CurDir** function to return the current path.

```
' Assume current path on C drive is "C:\WINDOWS\SYSTEM".
' Assume current path on D drive is "D:\EXCEL".
' Assume C is the current drive.
Dim MyPath As String
MyPath = CurDir()   ' Returns "C:\WINDOWS\SYSTEM".
MyPath = CurDir("C"c)   ' Returns "C:\WINDOWS\SYSTEM".
MyPath = CurDir("D"c)   ' Returns "D:\EXCEL".
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in MicrosoftVisualBasic.dll)

D-G Functions

The following table contains a listing of the Visual Basic .NET run-time member functions.

DateAdd	DateDiff	DatePart	DateSerial
DateValue	Day	DDB	DeleteSetting
Derived Math	Dir	Environ	EOF
ErrorToString	Exp	FileAttr	FileClose
FileCopy	FileDateTime	FileGet	FileGetObject
FileLen	FileOpen	FilePut	FilePutObject
FileWidth	Filter	Fix	Format
FormatCurrency	FormatDateTime	FormatNumber	FormatPercent
FreeFile	FV	GetAllSettings	GetAttr
GetChar	GetException	GetObject	GetSetting

See Also

A-C Functions | H-L Functions | M-R Functions | S-Z Functions | Visual Basic Language and Run-Time Reference

DateAdd Function

Returns a **Date** value containing a date and time value to which a specified time interval has been added.

```
Public Overloads Function DateAdd( _
   ByVal Interval As DateInterval, _
   ByVal Number As Double, _
   ByVal DateValue As DateTime _
) As DateTime
```

-or-

```
Public Overloads Function DateAdd( _
   ByVal Interval As String, _
   ByVal Number As Double, _
   ByVal DateValue As Object _
) As DateTime
```

Parameters

Interval
Required. **DateInterval** enumeration value or **String** expression representing the time interval you want to add.

Number
Required. **Double**. Floating-point expression representing the number of intervals you want to add. *Number* can be positive (to get date/time values in the future) or negative (to get date/time values in the past). It can contain a fractional part when *Interval* specifies hours, minutes, or seconds. For other values of *Interval*, any fractional part of *Number* is ignored.

DateValue
Required. **Date**. An expression representing the date and time to which the interval is to be added. *DateValue* itself is not changed in the calling program.

Settings

The *Interval* argument can have one of the following settings.

Enumeration value	String	Unit of time interval to add
DateInterval.Day	d	Day; truncated to integral value
DateInterval.DayOfYear	y	Day; truncated to integral value
DateInterval.Hour	h	Hour; rounded to nearest millisecond
DateInterval.Minute	n	Minute; rounded to nearest millisecond
DateInterval.Month	m	Month; truncated to integral value
DateInterval.Quarter	q	Quarter; truncated to integral value
DateInterval.Second	s	Second; rounded to nearest millisecond
DateInterval.Weekday	w	Day; truncated to integral value
DateInterval.WeekOfYear	ww	Week; truncated to integral value
DateInterval.Year	yyyy	Year; truncated to integral value

Exceptions/Errors

Exception type	Error number	Condition
InvalidCastException	13	*DateValue* is not coercible to **Date.**
ArgumentException	5	*Interval* is invalid.
ArgumentOutOfRangeException	9	Calculated date is before 00:00:00 on January 1 of the year 1, or later than 23:59:59 on December 31, 9999.

Remarks

You can use the **DateAdd** function to add or subtract a specified time interval from a date. For example, you can calculate a date

30 days from today or a time 45 minutes before now.

To add days to *DateValue*, you can use **DateInterval.Day**, **DateInterval.DayOfYear**, or **DateInterval.Weekday**. These are treated as equivalent because **DayOfYear** and **Weekday** are not meaningful time intervals.

The **DateAdd** function never returns an invalid date. If necessary, the day part of the resulting date is adjusted downward to the last day of the resulting month in the resulting year. The following example adds one month to January 31:

```
Dim NextMonth As Date = DateAdd(DateInterval.Month, 1, #1/31/1995#)
```

In this example, **DateAdd** returns `#2/28/1995#`, not `#2/31/1995#`. If *DateValue* is `#1/31/1996#`, it returns `#2/29/1996#` because 1996 is a leap year.

If any argument has an invalid value, an **ArgumentException** error occurs. If the calculated date is earlier than 00:00:00 on January 1 of the year 1, or later than 23:59:59 on December 31, 9999, an **ArgumentOutOfRangeException** error occurs. If the *DateValue* argument has a value that cannot be coerced to a valid **Date** value, an **InvalidCastException** error occurs.

> **Note** **DateAdd** uses the current calendar setting from the **CurrentCulture** property of the **CultureInfo** class in the **System.Globalization** namespace. The default **CurrentCulture** values are determined by **Control Panel** settings.

Since every **Date** value is supported by a **DateTime** structure, its methods give you additional options in adding time intervals. For example, you can add a fractional number of days, rounded to the nearest millisecond, to a **Date** variable as follows:

```
Dim NextTime As Date = Now        ' Current date and time.
NextTime = NextTime.AddDays(3.4)  ' Increment by 3 2/5 days.
```

Example

This example takes a date and, using the **DateAdd** function, displays a corresponding date a specified number of months in the future.

```
Dim Msg, Number, StartDate As String   'Declare variables.
Dim Months As Double
Dim SecondDate As Date
Dim IntervalType As DateInterval
IntervalType = DateInterval.Month   ' Specifies months as interval.
StartDate = InputBox("Enter a date")
SecondDate = CDate(StartDate)
Number = InputBox("Enter number of months to add")
Months = Val(Number)
Msg = "New date: " & DateAdd(IntervalType, Months, SecondDate)
MsgBox (Msg)
```

Requirements

Namespace: Microsoft.VisualBasic

Module: DateAndTime

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

DateDiff Function | DatePart Function | Day Function | Format Function | Now Property | Weekday Function | Year Function | Date Data Type | System Namespace | System.Globalization Namespace | DateTime Structure | ArgumentException Class | ArgumentOutOfRangeException Class | InvalidCastException Class | CultureInfo Class

DateDiff Function

Returns a **Long** value specifying the number of time intervals between two **Date** values.

```
Public Overloads Function DateDiff( _
   ByVal Interval As DateInterval, _
   ByVal Date1 As DateTime, _
   ByVal Date2 As DateTime, _
   Optional ByVal DayOfWeek As FirstDayOfWeek = FirstDayOfWeek.Sunday, _
   Optional ByVal  WeekOfYear As FirstWeekOfYear = FirstWeekOfYear.Jan1 _
) As Long
```

-or-

```
Public Overloads Function DateDiff( _
   ByVal Interval As String, _
   ByVal Date1 As Object, _
   ByVal Date2 As Object, _
   Optional ByVal DayOfWeek As FirstDayOfWeek = FirstDayOfWeek.Sunday, _
   Optional ByVal WeekOfYear As FirstWeekOfYear = FirstWeekOfYear.Jan1 _
) As Long
```

Parameters

Interval
Required. **DateInterval** enumeration value or **String** expression representing the time interval you want to use as the unit of difference between *Date1* and *Date2*.

Date1, *Date2*
Required. **Date**. The two date/time values you want to use in the calculation. The value of *Date1* is subtracted from the value of *Date2* to produce the difference. Neither value is changed in the calling program.

DayOfWeek
Optional. A value chosen from the **FirstDayOfWeek** enumeration that specifies the first day of the week. If not specified, **FirstDayOfWeek.Sunday** is used.

WeekOfYear
Optional. A value chosen from the **FirstWeekOfYear** enumeration that specifies the first week of the year. If not specified, **FirstWeekOfYear.Jan1** is used.

Settings

The *Interval* argument can have one of the following settings.

Enumeration value	String	Unit of time difference
DateInterval.Day	d	Day
DateInterval.DayOfYear	y	Day
DateInterval.Hour	h	Hour
DateInterval.Minute	n	Minute
DateInterval.Month	m	Month
DateInterval.Quarter	q	Quarter
DateInterval.Second	s	Second
DateInterval.Weekday	w	Week
DateInterval.WeekOfYear	ww	Calendar week
DateInterval.Year	yyyy	Year

The *DayOfWeek* argument can have one of the following settings.

Enumeration value	Value	Description
FirstDayOfWeek.System	0	First day of week specified in system settings
FirstDayOfWeek.Sunday	1	Sunday (default)

FirstDayOfWeek.Monday	2	Monday (complies with ISO standard 8601, section 3.17)
FirstDayOfWeek.Tuesday	3	Tuesday
FirstDayOfWeek.Wednesday	4	Wednesday
FirstDayOfWeek.Thursday	5	Thursday
FirstDayOfWeek.Friday	6	Friday
FirstDayOfWeek.Saturday	7	Saturday

The *WeekOfYear* argument can have one of the following settings.

Enumeration value	Value	Description
FirstWeekOfYear.System	0	First week of year specified in system settings
FirstWeekOfYear.Jan1	1	Week in which January 1 occurs (default)
FirstWeekOfYear.FirstFourDays	2	Week that has at least four days in the new year (complies with ISO standard 8601, section 3.17)
FirstWeekOfYear.FirstFullWeek	3	First full week in the new year

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	Invalid *Interval*.
ArgumentException	5	*Date* or *DayofWeek* are out of range .
InvalidCastException	13	*Date1* or *Date2* are invalid types.

Remarks

You can use the **DateDiff** function to determine how many specified time intervals exist between two date/time values. For example, you might use **DateDiff** to calculate the number of days between two dates, or the number of weeks between today and the end of the year.

If *Interval* is set to **DateInterval.DayOfYear**, it is treated the same as **DateInterval.Day**, because **DayOfYear** is not a meaningful unit for a time interval.

If *Interval* is set to **DateInterval.WeekOfYear**, the return value represents the number of weeks between the first day of the week containing *Date1* and the first day of the week containing *Date2*. The following example shows how this produces different results from **DateInterval.Weekday**.

```
Dim DatTim1 As Date = #1/4/2001#   ' This is a Thursday.
Dim DatTim2 As Date = #1/9/2001#   ' This is the next Tuesday.
' Assume Sunday is specified as first day of the week.
Dim WD As Long = DateDiff(DateInterval.Weekday, DatTim1, DatTim2)
Dim WY As Long = DateDiff(DateInterval.WeekOfYear, DatTim1, DatTim2)
```

In the preceding example, **DateDiff** returns **0** to `WD` because the difference between the two dates is less than seven days, but it returns **1** to `WY` because there is a seven-day difference between the first days of the respective calendar weeks.

If *Interval* is set to **DateInterval.Year**, the return value is calculated purely from the year parts of *Date1* and *Date2*.

Because *Date1* and *Date2* are of the **Date** data type, they hold date and time values accurate to 100-nanosecond ticks on the system timer. However, **DateDiff** always returns the number of time intervals as a **Long** value.

If *Date1* represents a later date and time than *Date2*, **DateDiff** returns a negative number.

If any argument has an invalid value, an **ArgumentException** error occurs. If either the *Date1* or *Date2* argument has a value that cannot be coerced to a valid **Date** value, an **InvalidCastException** error occurs.

> **Note** When comparing December 31 to January 1 of the following year, **DateDiff** returns 1 for **DateInterval.Year**, **DateInterval.Quarter**, or **DateInterval.Month**, even though only one day has elapsed.

Since every **Date** value is supported by a **DateTime** structure, its methods give you additional options in finding time intervals. For example, you can use the **Subtract** method in either of its overloaded forms. One of these subtracts a **TimeSpan** from a **Date** variable to return another **Date** value; the other subtracts a **Date** value to return a **TimeSpan**. You can time a process to find out

how many milliseconds it takes, as follows:

```
Dim StartTime As Date = Now   ' Starting date/time.
' Run the process that is to be timed.
Dim RunLength As System.TimeSpan = Now.Subtract(StartTime)
Dim Millisecs As Integer = RunLength.Milliseconds
```

Example

This example uses the **DateDiff** function to display the number of days between a given date and today.

```
Dim FirstDate, Msg As String   ' Declare variables.
Dim SecondDate As Date
FirstDate = InputBox("Enter a date")
SecondDate = CDate(FirstDate)
Msg = "Days from today: " & DateDiff(DateInterval.Day, Now, SecondDate)
MsgBox (Msg)
```

Requirements

Namespace: Microsoft.VisualBasic

Module: DateAndTime

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

DateAdd Function | DatePart Function | Day Function | Format Function | Now Property | Weekday Function | Year Function | Date Data Type | System Namespace | DateTime Structure | TimeSpan Structure | ArgumentException Class | InvalidCastException Class

DatePart Function

Returns an **Integer** value containing the specified component of a given **Date** value.

```
Public Overloads Function DatePart( _
   ByVal Interval As DateInterval, _
   ByVal DateValue As DateTime, _
   Optional ByVal FirstDayOfWeekValue As FirstDayOfWeek = VbSunday, _
   Optional ByVal FirstWeekOfYearValue As FirstWeekOfYear = VbFirstJan1 _
) As Integer
```

-or-

```
Public Overloads Function DatePart( _
    ByVal Interval As String, _
   ByVal DateValue As Object, _
   Optional ByVal DayOfWeek As FirstDayOfWeek = FirstDayOfWeek.Sunday, _
   Optional ByVal WeekOfYear As FirstWeekOfYear = FirstWeekOfYear.Jan1 _
) As Integer
```

Parameters

Interval
Required. **DateInterval** enumeration value or **String** expression representing the part of the date/time value you want to return.

DateValue
Required. **Date** value that you want to evaluate.

FirstDayOfWeekValue
Optional. A value chosen from the **FirstDayOfWeek** enumeration that specifies the first day of the week. If not specified, **FirstDayOfWeek.Sunday** is used.

FirstWeekOfYearValue
Optional. A value chosen from the **FirstWeekOfYear** enumeration that specifies the first week of the year. If not specified, **FirstWeekOfYear.Jan1** is used.

Settings

The *Interval* argument can have one of the following settings.

Enumeration value	String	Part of date/time value to return
DateInterval.Day	d	Day of month (1 through 31)
DateInterval.DayOfYear	y	Day of year (1 through 366)
DateInterval.Hour	h	Hour
DateInterval.Minute	n	Minute
DateInterval.Month	m	Month
DateInterval.Quarter	q	Quarter
DateInterval.Second	s	Second
DateInterval.Weekday	w	Day of week (1 through 7)
DateInterval.WeekOfYear	ww	Week of year (1 through 53)
DateInterval.Year	yyyy	Year

The *FirstDayOfWeekValue* argument can have one of the following settings.

Enumeration value	Value	Description
FirstDayOfWeek.System	0	First day of week specified in system settings
FirstDayOfWeek.Sunday	1	Sunday (default)
FirstDayOfWeek.Monday	2	Monday (complies with ISO standard 8601, section 3.17)
FirstDayOfWeek.Tuesday	3	Tuesday
FirstDayOfWeek.Wednesday	4	Wednesday

FirstDayOfWeek.Thursday	5	Thursday
FirstDayOfWeek.Friday	6	Friday
FirstDayOfWeek.Saturday	7	Saturday

The *FirstWeekOfYearValue* argument can have one of the following settings.

Enumeration value	Value	Description
FirstWeekOfYear.System	0	First week of year specified in system settings
FirstWeekOfYear.Jan1	1	Week in which January 1 occurs (default)
FirstWeekOfYear.FirstFourDays	2	Week that has at least four days in the new year (complies with ISO standard 8601, section 3.17)
FirstWeekOfYear.FirstFullWeek	3	First full week in new year

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Interval* is invalid.
InvalidCastException	13	*DateValue* is not coercible to **Date**.

Remarks

You can use the **DatePart** function to evaluate a date/time value and return a specific component. For example, you might use **DatePart** to calculate the day of the week or the current hour.

If you choose **DateInterval.Weekday** for the *Interval* argument, the returned value is consistent with the values of the **FirstDayOfWeek** enumeration. If you choose **DateInterval.WeekOfYear**, **DatePart** uses the **Calendar** and **CultureInfo** classes of the **System.Globalization** namespace to determine your current settings.

The *FirstDayOfWeekValue* argument affects calculations that use the **DateInterval.Weekday** and **DateInterval.WeekOfYear** *Interval* settings. The *FirstWeekOfYearValue* argument affects calculations that specify **DateInterval.WeekOfYear** for *Interval*.

If any argument has an invalid value, an **ArgumentException** error occurs. If the *DateValue* argument has a value that cannot be coerced to a valid **Date** value, an **InvalidCastException** error occurs.

Since every **Date** value is supported by a **DateTime** structure, its methods give you additional options in retrieving date/time parts. For example, you can obtain the entire date value of a **Date** variable, with the time value set to midnight, as follows:

```
Dim CurrDatTim As Date = Now   ' Current date and time.
Dim LastMidnight As Date = CurrDatTim.Date   ' At midnight.
```

Example

This example takes a date and, using the **DatePart** function, displays the quarter of the year in which it occurs.

```
Dim FirstDate, Msg As String   'Declare variables.
Dim SecondDate As Date
FirstDate = InputBox("Enter a date:")
SecondDate = CDate(FirstDate)
Msg = "Quarter: " & DatePart(DateInterval.Quarter, SecondDate)
MsgBox (Msg)
```

Requirements

Namespace: Microsoft.VisualBasic

Module: DateAndTime

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

DateAdd Function | DateDiff Function | Day Function | Format Function | Now Property | Weekday Function | Year Function | Date Data Type | System Namespace | DateTime Structure | Calendar Class | CultureInfo Class | ArgumentException Class | InvalidCastException Class

DateSerial Function

Returns a **Date** value representing a specified year, month, and day, with the time information set to midnight (00:00:00).

```
Public Function DateSerial( _
   ByVal [Year] As Integer, _
   ByVal [Month] As Integer, _
   ByVal [Day] As Integer _
) As DateTime
```

Parameters

Year
Required. **Integer** expression from 1 through 9999. However, values below this range are also accepted. If *Year* is 0 through 99, it is interpreted as being between 1930 and 2029, as explained in the Remarks section below. If *Year* is less than 1, it is subtracted from the current year.

Month
Required. **Integer** expression from 1 through 12. However, values outside this range are also accepted. The value of *Month* is offset by 1 and applied to January of the calculated year. In other words, (*Month* - 1) is added to January. The year is recalculated if necessary. The following results illustrate this effect:

- If *Month* is 1, the result is January of the calculated year.
- If *Month* is 0, the result is December of the previous year.
- If *Month* is -1, the result is November of the previous year.
- If *Month* is 13, the result is January of the following year.

Day
Required. **Integer** expression from 1 through 31. However, values outside this range are also accepted. The value of *Day* is offset by 1 and applied to the first day of the calculated month. In other words, (*Day* - 1) is added to the first of the month. The month and year are recalculated if necessary. The following results illustrate this effect:

- If *Day* is 1, the result is the first day of the calculated month.
- If *Day* is 0, the result is the last day of the previous month.
- If *Day* is -1, the result is the penultimate day of the previous month.
- If *Day* is past the end of the current month, the result is the appropriate day of the following month. For example, if *Month* is 4 and *Day* is 31, the result is May 1.

Remarks

Under Windows® 98 or Windows 2000, two-digit years for the *Year* argument are interpreted based on user-defined machine settings. The default settings are that values from 0 through 29 are interpreted as the years 2000–2029, and values from 30 through 99 are interpreted as the years 1930–1999. For all other *Year* arguments, use a four-digit year; for example, 1924.

Earlier versions of Windows interpret two-digit years based on the defaults described previously. To be sure the function returns the proper value, use a four-digit *Year*.

The following example demonstrates negative, zero, and positive argument values. Here, the **DateSerial** function returns a **Date** representing the day before the first day of March in the year 10 years before the current year; in other words, the last day of February ten years ago.

```
Dim EndFeb As Date = DateSerial(-10, 3, 0)
```

If either *Month* or *Day* exceeds its normal range, it is applied to the next larger unit as appropriate. For example, if you specify 32 days, it is evaluated as one month and from one to four days, depending on the value of *Month*. If *Year* is greater than 9999, or if any argument is outside the range -2,147,483,648 through 2,147,483,647, an **ArgumentException** error occurs. If the date specified by the three arguments is earlier than 00:00:00 on January 1 of the year 1, or later than 23:59:59 on December 31, 9999, an **ArgumentOutOfRangeException** error occurs.

The **Date** data type includes time components. **DateSerial** sets all of these to 0, so the returned value represents the beginning of the calculated day.

Since every **Date** value is supported by a **DateTime** structure, its methods give you additional options in assembling a **Date** value. For example, you can use one of the overloaded **DateTime** constructors to populate a **Date** variable using the desired combination of components. The following example sets `NewDateTime` to May 6, 1978 at one tenth of a second before 8:30 in the morning:

```
Dim NewDateTime As Date = New Date(1978, 5, 6, 8, 29, 59, 900)
```

Example

This example uses the **DateSerial** function to return the date for the specified year, month, and day.

```
Dim MyDate As Date
' MyDate contains the date for February 12, 1969.
MyDate = DateSerial(1969, 2, 12)   ' Return a date.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: DateAndTime

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

DateValue Function | Day Function | Month Function | Now Property | TimeSerial Function | TimeValue Function | Weekday Function | Year Function | Date Data Type | System Namespace | DateTime Structure | ArgumentException Class | ArgumentOutOfRangeException Class

DateValue Function

Returns a **Date** value containing the date information represented by a string, with the time information set to midnight (00:00:00).

```
Public Function DateValue(ByVal StringDate As String) As DateTime
```

Parameter

StringDate
Required. **String** expression representing a date/time value from 00:00:00 on January 1 of the year 1 through 23:59:59 on December 31, 9999.

Exceptions/Errors

Exception type	Error number	Condition
InvalidCastException	13	*StringDate* includes invalid time informatio n.

Remarks

If *StringDate* includes only numbers from 1 through 12 separated by valid date separators, **DateValue** recognizes the order for month, day, and year according to the Short Date format specified for your system. **DateValue** uses the current calendar setting from the **CurrentCulture** property of the **CultureInfo** class in the **System.Globalization** namespace. The default **CurrentCulture** values are determined by **Control Panel** settings. You can override the Short Date format by setting the **ShortDatePattern** property of the **DateTimeFormatInfo** class in the **System.Globalization** namespace.

DateValue recognizes month names in long, abbreviated, and numeric form. For example, in addition to recognizing 12/30/1991 and 12/30/91, **DateValue** also recognizes December 30, 1991 and Dec 30, 1991.

If the year part of *StringDate* is omitted, **DateValue** uses the current year from your computer's system date.

If the *StringDate* argument includes time information, **DateValue** does not include it in the returned value. However, if *StringDate* includes invalid time information, such as "89:98", an **InvalidCastException** error occurs.

Example

This example uses the **DateValue** function to convert a string to a date. You can also use date literals to directly assign a date to an **Object** or **Date** variable, for example, `MyDate = #2/12/69#`.

```
Dim MyDate As Date
MyDate = DateValue("February 12, 1969")   ' Returns a date.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: DateAndTime

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

DateSerial Function | Day Function | Month Function | Now Property | TimeSerial Function | TimeValue Function | Weekday Function | Year Function | Date Data Type | System Namespace | System.Globalization Namespace | DateTime Structure | InvalidCastException Class | CultureInfo Class | DateTimeFormatInfo Class

Day Function

Returns an **Integer** value from 1 through 31 representing the day of the month.

```
Public Function Day(ByVal DateValue As DateTime) As Integer
```

Parameter

DateValue
Required. **Date** value from which you want to extract the day.

Remarks

If you use the **Day** function, you might have to qualify it with the **Microsoft.VisualBasic** namespace, because the **System.Windows.Forms** namespace defines **Day** as an enumeration. The following example shows how qualifying **Day** resolves this ambiguity:

```
Dim ThisDay As Integer = Microsoft.VisualBasic.DateAndTime.Day(Now)
```

You can also obtain the day of the month by calling **DatePart** and specifying **DateInterval.Day** for the *Interval* argument.

Example

This example uses the **Day** function to obtain the day of the month from a specified date. In the development environment, the date literal is displayed in standard short format (such as "02/12/1969") using the locale settings of your code.

```
Dim MyDate As Date
Dim MyDay As Integer
MyDate = #2/12/1969#   ' Assign a date using standard short format.
MyDay = Microsoft.VisualBasic.DateAndTime.Day(MyDate)   ' MyDay contains 12.
```

Day is qualified to distinguish it from the **System.Windows.Forms.Day** enumeration.

Requirements

Namespace: Microsoft.VisualBasic

Module: DateAndTime

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Hour Function | Minute Function | Month Function | Now Property | Second Function | Weekday Function | Year Function | DatePart Function | System Namespace | System.Windows.Forms Namespace | DateTime Structure | ArgumentException Class | ArgumentOutOfRangeException Class

DDB Function

Returns a **Double** specifying the depreciation of an asset for a specific time period using the double-declining balance method or some other method you specify.

```
Function DDB( _
   ByVal Cost As Double, _
   ByVal Salvage As Double, _
   ByVal Life As Double, _
   ByVal Period As Double, _
   Optional ByVal Factor As Double = 2.0 _
) As Double
```

Parameters

Cost
Required. **Double** specifying initial cost of the asset.
Salvage
Required. **Double** specifying value of the asset at the end of its useful life.
Life
Required. **Double** specifying length of useful life of the asset.
Period
Required. **Double** specifying period for which asset depreciation is calculated.
Factor
Optional. **Double** specifying rate at which the balance declines. If omitted, 2 (double-declining method) is assumed.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	Argument value < 0 or *Period* > *Life* .

Remarks

The double-declining balance method computes depreciation at an accelerated rate. Depreciation is highest in the first period and decreases in successive periods.

The *Life* and *Period* arguments must be expressed in the same units. For example, if *Life* is given in months, *Period* must also be given in months. All arguments must be positive numbers.

The **DDB** function uses the following formula to calculate depreciation for a given period:

```
Depreciation / Period = ((Cost - Salvage) * Factor) / Life
```

Example

This example uses the **DDB** function to return the depreciation of an asset for a specified period given the initial cost (`InitCost`), the salvage value at the end of the asset's useful life (`SalvageVal`), the total life of the asset in years (`LifeTime`), and the period in years for which the depreciation is calculated (`Depr`).

```
Sub testDDB()
   Dim InitCost, SalvageVal, MonthLife, DepYear As Double
   Dim Fmt As String
   Dim LifeTime, Depr As Double
   Const YRMOS As Integer = 12    ' Number of months in a year.
   Fmt = "###,##0.00"
   InitCost = CDbl(InputBox("What's the initial cost of the asset?"))
   SalvageVal = CDbl(InputBox("Enter the asset's value at end of its life."))
   MonthLife = CDbl(InputBox("What's the asset's useful life in months?"))
   Do While MonthLife < YRMOS   ' Ensure period is >= 1 year.
      MsgBox("Asset life must be a year or more.")
```

```
        MonthLife = CDbl(InputBox("What's the asset's useful life in months?"))
    Loop
    LifeTime = MonthLife / YRMOS   ' Convert months to years.
    If LifeTime <> Int(MonthLife / YRMOS) Then
        LifeTime = Int(LifeTime + 1)   ' Round up to nearest year.
    End If
    DepYear = CInt(InputBox("Enter year for depreciation calculation."))
    Do While DepYear < 1 Or DepYear > LifeTime
        MsgBox("You must enter at least 1 but not more than " & LifeTime)
        DepYear = CDbl(InputBox("Enter year for depreciation calculation."))
    Loop
    Depr = DDB(InitCost, SalvageVal, LifeTime, DepYear)
    MsgBox("The depreciation for year " & DepYear & " is " & _
    Format(Depr, Fmt) & ".")
End Sub
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Financial

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

DeleteSetting Function

Deletes a section or key setting from an application's entry in the Windows registry.

```
Public Sub DeleteSetting( _
   ByVal AppName As String, _
   Optional ByVal Section As String = Nothing, _
   Optional ByVal Key As String = Nothing _
)
```

Parameters

AppName
Required. **String** expression containing the name of the application or project to which the section or key setting applies.

Section
Required. **String** expression containing the name of the section from which the key setting is being deleted. If only *AppName* and *Section* are provided, the specified section is deleted along with all related key settings.

Key
Optional. **String** expression containing the name of the key setting being deleted.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Section*, *AppName*, or *Key* setting does not exist.
ArgumentException	5	User is not logged in.

Remarks

If all arguments are provided, the specified setting is deleted. A run-time error occurs if you attempt to use **DeleteSetting** on a nonexistent section or key setting.

DeleteSetting requires that a user be logged on since it operates under the HKEY_LOCAL_USER registry key, which is not active until a user logs on interactively.

Registry settings that are to be accessed from a non-interactive process (such as mtx.exe) should be stored under either the HKEY_LOCAL_MACHINE\Software\ or the HKEY_USER\DEFAULT\Software registry keys.

Example

The following example first uses the **SaveSetting** procedure to make entries in the Windows registry for the `MyApp` application, and then uses the **DeleteSetting** function to remove them. Because no *Key* argument is specified, the whole `Startup` section is deleted, including the section name and all of its keys.

```
' Place some settings in the registry.
SaveSetting("MyApp", "Startup", "Top", "75")
SaveSetting("MyApp","Startup", "Left", "50")
' Remove section and all its settings from registry.
DeleteSetting ("MyApp", "Startup")
' Remove MyApp from the registry.
DeleteSetting ("MyApp")
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: Interaction

Assembly: Microsoft.Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

GetAllSettings Function | GetSetting Function | SaveSetting Function | ArgumentException Class

Dir Function

Returns a string representing the name of a file, directory, or folder that matches a specified pattern or file attribute, or the volume label of a drive.

```
Public Overloads Function Dir() As String
```

-or-

```
Public Overloads Function Dir( _
   Optional ByVal PathName As String, _
   Optional ByVal Attributes As FileAttribute = FileAttribute.Normal _
) As String
```

Parameters

PathName
Optional. **String** expression that specifies a file name, directory or folder name, or drive volume label. A zero-length string ("") is returned if *PathName* is not found.

Attributes
Optional. Enumeration or numeric expression whose value specifies file attributes. If omitted, returns files that match *PathName,* but have no attributes.

Settings

The *Attributes* argument enumeration values are as follows:

Value	Constant	Description
Normal	**vbnormal**	Default. Specifies files with no attributes.
ReadOnly	**vbReadOnly**	Specifies read-only files in addition to files with no attributes.
Hidden	**vbHidden**	Specifies hidden files in addition to files with no attributes.
System	**vbSystem**	Specifies system files in addition to files with no attributes.
Volume	**vbVolume**	Specifies volume label; if any other attribute is specified, **vbVolume** is ignored.
Directory	**vbDirectory**	Specifies directories or folders in addition to files with no attributes.
Archive	**vbArchive**	File has changed since last backup.
Alias	**vbAlias**	File has a different name.

> **Note** These enumerations are specified by the Visual Basic language and can be used anywhere in your code in place of the actual values.

Remarks

The **Dir** function supports the use of multiple-character (*****) and single-character (?) wildcards to specify multiple files.

You must supply a **PathName** the first time you call the **Dir** function. Subsequent calls to the **Dir** function may be made with no parameters to retrieve the next item.

> **Security Note** Do not make decisions about the contents of a file based on the file name extension. For example, a file named Form1.vb may not be a Visual Basic .NET source file.

Example

This example uses the **Dir** function to check if certain files and directories exist.

```
Dim MyFile, MyPath, MyName
' Returns "WIN.INI" if it exists.
MyFile = Dir("C:\WINDOWS\WIN.INI")
```

```
' Returns filename with specified extension. If more than one *.INI
' file exists, the first file found is returned.
MyFile = Dir("C:\WINDOWS\*.INI")

' Call Dir again without arguments to return the next *.INI file in the
' same directory.
MyFile = Dir()

' Return first *.TXT file, including files with a set hidden attribute.
MyFile = Dir("*.TXT", vbHidden)

' Display the names in C:\ that represent directories.
MyPath = "c:\"   ' Set the path.
MyName = Dir(MyPath, vbDirectory)   ' Retrieve the first entry.
Do While MyName <> ""   ' Start the loop.
      ' Use bitwise comparison to make sure MyName is a directory.
      If (GetAttr(MyPath & MyName) And vbDirectory) = vbDirectory Then
         ' Display entry only if it's a directory.
         Debug.WriteLine(MyName)
      End If
   MyName = Dir()   ' Get next entry.
Loop
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in MicrosoftVisualBasic.dll)

ChDir Function | CurDir Function | FileAttribute Enumeration

Environ Function

Returns the string associated with an operating system environment variable.

```
Overloads Function Environ(ByVal Expression As Integer) As String
```

-or-

```
Overloads Function Environ(ByVal Expression As String) As String
```

Parameter

Expression
Required. Expression that evaluates to either a string containing the name of an environment variable, or an integer corresponding to the numeric order of an environment string in the environment-string table.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Expression* is missing.

Remarks

If *Expression* contains a string, the **Environ** function returns the text assigned to the specified environment string; that is, the text following the equal sign (=) in the environment-string table for that environment variable. If the string in *Expression* cannot be found in the environment-string table, a zero-length string ("") is returned.

If *Expression* contains an integer, the string occupying that numeric position in the environment-string table is returned. In this case, **Environ** returns all of the text, including the name of the environment variable. If there is no environment string in the specified position, **Environ** returns a zero-length string.

Example

This example uses the **Environ** function to supply the entry number and length of the `PATH` statement from the environment-string table.

```
Sub tenv()
   Dim envString As String
   Dim found As Boolean = False
   Dim index As Integer = 1
   Dim pathLength As Integer
   Dim message As String

   envString = Environ(index)
   While Not found And (envString <> "")
      If (envString.Substring(0, 5) = "Path=") Then
         found = True
      Else
         index += 1
         envString = Environ(index)
      End If
   End While

   If found Then
      pathLength = Environ("PATH").Length
      message = "PATH entry = " & index & " and length = " & pathLength
   Else
      message = "No PATH environment variable exists."
   End If
```

```
    MsgBox(message)
End Sub
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: Interaction

Assembly: Microsoft Visual Basic .NET Runtime (in MicrosoftVisualBasic.dll)

Visual Basic Run-Time Library Members | ArgumentException Class

EOF Function

Returns a Boolean value **True** when the end of a file opened for **Random** or sequential **Input** has been reached.

```
Public Function EOF(ByVal FileNumber As Integer) As Boolean
```

Parameter

FileNumber
Required. An **Integer** containing any valid file number.

Exceptions/Errors

Exception type	Error number	Condition
IOException	52	*FileNumber* does not exist.
IOException	54	File mode is invalid.

Remarks

Use **EOF** to avoid the error generated by attempting to get input past the end of a file.

The **EOF** function returns **False** until the end of the file has been reached. With files opened for **Random** or **Binary** access, **EOF** returns **False** until the last executed **FileGet** function is unable to read an entire record.

With files opened for **Binary** access, an attempt to read through the file using the **Input** function until **EOF** returns **True** generates an error. Use the **LOF** and **Loc** functions instead of **EOF** when reading binary files with **Input**, or use **Get** when using the **EOF** function. With files opened for **Output**, **EOF** always returns **True**.

Example

This example uses the **EOF** function to detect the end of a file. This example assumes that `TESTFILE` is a text file with a few lines of text.

```
Dim TextLine As String
FileOpen(1, "TESTFILE", OpenMode.Input)   ' Open file.
Do While Not EOF(1)   ' Loop until end of file.
   TextLine = LineInput(1)   ' Read line into variable.
   Debug.WriteLine(TextLine)   ' Print to the Command window.
Loop
FileClose(1)   ' Close file.
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

FileGet Function | Loc Function | LOF Function | FileOpen Function | IOException Class

ErrorToString Function

Returns the error message that corresponds to a given error number.

```
Public Shared Function ErrorToString(ByVal errornumber As Integer) As String
```

Parameter

errornumber
Optional. Any valid error number.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*ErrorNumber* is out of range.

Remarks

The **ErrorToString** function examines the property settings of the **Err** object to identify the most recent run-time error. The return value of the **ErrorToString** function corresponds to the **Description** property of the **Err** object. If *errornumber* is a valid error number but is not defined, **ErrorToString** returns the string, "Application-defined or object-defined error." If *errornumber* is not valid, an error occurs. If *errornumber* is omitted, the message corresponding to the most recent run-time error is returned. If no run-time error has occurred, or *errornumber* is 0, **ErrorToString** returns a zero-length string ("").

In Visual Basic version 6.0 and earlier, this functionality was provided by the **Error** function.

Example

The following code uses the **ErrorToString** function to display error messages that correspond to the specified error numbers:

```
Dim ErrorNumber As Integer
For ErrorNumber = 61 To 64   ' Loop through values 61 - 64.
   MsgBox(ErrorToString(ErrorNumber))   ' Display error names in message box.
Next ErrorNumber
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Conversion

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Math Functions

The math functions in Visual Basic 6 have been replaced by equivalent methods in the **System.Math** class of the .NET Framework.

Remarks

The .NET Framework math methods are functionally identical to their Visual Basic 6 counterparts, although some have slightly different names. For example, the .NET Framework equivalent of the Visual Basic 6 Atn function is **Atan**. The following table lists the Visual Basic 6 math function names and the equivalent .NET Framework methods.

Visual Basic 6 function	Visual Basic .NET method	Description
Abs	Math.Abs Method	Returns the absolute value of a specified number.
Atn	Math.Atan Method	Returns a **Double** value containing the angle whose tangent is the specified number.
Cos	Math.Cos Method	Returns a **Double** value containing the cosine of the specified angle.
Exp	Math.Exp Method	Returns a **Double** value containing e (the base of natural logarithms) raised to the specified power.
Log	Math.Log Method	Returns a **Double** value containing the logarithm of a specified number. This method is overloaded and can return either the natural (base e) logarithm of a specified number or the logarithm of a specified number in a specified base.
Round	Math.Round Method	Returns a **Double** value containing the number nearest the specified value. Additional round functions are available as methods of the intrinsic types such as Decimal.Round Method.
Sgn	Math.Sign Method	Returns an **Integer** value indicating the sign of a number.
Sin	Math.Sin Method	Returns a **Double** value specifying the sine of an angle.
Sqr	Math.Sqrt Method	Returns a **Double** value specifying the square root of a number.
Tan	Math.Tan Method	Returns a **Double** value containing the tangent of an angle.

In addition, the .NET Framework math class provides constants and other static methods for trigonometric, logarithmic, and other common mathematical functions. All of these can be used in a Visual Basic program.

To use these functions without qualification, import the **System.Math** namespace into your project by adding the following code to the top of the source code:

```
Imports System.Math
```

Requirements

Class: Math Class

Abs Example

This example uses the **Abs** method of the **Math** class to compute the absolute value of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyNumber As Double
```

```
MyNumber = Abs(50.3)    ' Returns 50.3.
MyNumber = Abs(-50.3)   ' Returns 50.3.
```

Atan Example

This example uses the **Atan** method of the **Math** class to calculate the value of pi.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim pi As Double
pi = 4 * Atan(1)   ' Calculate the value of pi.
```

Cos Example

This example uses the **Cos** method of the **Math** class to return the cosine of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MySecant As Double
MyAngle = 1.3   ' Define angle in radians.
MySecant = 1 / Cos(MyAngle)   ' Calculate secant.
```

Exp Example

This example uses the **Exp** method of the **Math** class to return *e* raised to a power.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyHSin As Double
' Define angle in radians.
MyAngle = 1.3
' Calculate hyperbolic sine.
MyHSin = (Exp(MyAngle) - Exp(-1 * MyAngle)) / 2
```

Log Example

This example uses the **Log** method of the **Math** class to return the natural logarithm of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyLog As Double
' Define angle in radians.
MyAngle = 1.3
' Calculate inverse hyperbolic sine.
MyLog = Log(MyAngle + Sqrt(MyAngle * MyAngle + 1))
```

Round Example

This example uses the **Round** method of the **Math** class to round a number to the nearest integer.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyVar1 As Double = 2.8
Dim MyVar2 As Double
MyVar2 =Round(MyVar1)   ' Returns 3.
```

Sign Example

This example uses the **Sign** method of the **Math** class to determine the sign of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyVar1, MyVar2, MyVar3 As Double
Dim MySign As Integer
MyVar1 = 12
MyVar2 = -2.4
MyVar3 = 0
MySign = Sign(MyVar1)   ' Returns 1.
MySign = Sign(MyVar2)   ' Returns -1.
MySign = Sign(MyVar3)   ' Returns 0.
```

Sin Example

This example uses the **Sin** method of the **Math** class to return the sine of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyCosecant As Double
MyAngle = 1.3   ' Define angle in radians.
MyCosecant = 1 / Sin(MyAngle)   ' Calculate cosecant.
```

Sqrt Example

This example uses the **Sqrt** method of the **Math** class to calculate the square root of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MySqr As Double
MySqr = Sqrt(4)    ' Returns 2.
MySqr = Sqrt(23)   ' Returns 4.79583152331272.
MySqr = Sqrt(0)    ' Returns 0.
MySqr = Sqrt(-4)   ' Returns NaN (not a number).
```

Tan Example

This example uses the **Tan** method of the **Math** class to return the tangent of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyCotangent As Double
MyAngle = 1.3   ' Define angle in radians.
MyCotangent = 1 / Tan(MyAngle)   ' Calculate cotangent.
```

Requirements

Namespace: System.Math

Assembly: mscorlib (in mscorlib.dll)

See Also

Rnd Function | Randomize Statement | Derived Math Functions | Double.NaN Field

FileAttr Function

Returns an enumeration representing the file mode for files opened using the **FileOpen** function.

```
Public Function FileAttr(ByVal FileNumber As Integer) As OpenMode
```

Parameter

FileNumber
Required. **Integer**. Any valid file number.

Exceptions/Errors

Exception type	Error number	Condition
IOException	52	*FileNumber* does not exist.
IOException	54	File mode is invalid.

Return Values

The following enumeration values indicate the file access mode:

Value	Mode
1	**OpenMode.Input**
2	**OpenMode.Output**
4	**OpenMode.Random**
8	**OpenMode.Append**
32	**OpenMode.Binary**

Example

This example uses the **FileAttr** function to return the file mode of an open file.

```
Dim mode As OpenMode
FileOpen(1, "c:\MYFILE.TXT", OpenMode.Input)
mode = FileAttr(1)
MsgBox("The file mode is " & mode.ToString())
FileClose(1)
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

GetAttr Function | FileOpen Function | SetAttr Function | IOException Class

FileClose Function

Concludes input/output (I/O) to a file opened using the **FileOpen** function.

```
Public Sub FileClose(ParamArray FileNumbers() As Integer)
```

Parameter

FileNumbers()
Optional. Parameter array of 0 or more channels to be closed.

Exceptions/Errors

Exception type	Error number	Condition
IOException	52	*FileNumber* does not exist.

Remarks

If you omit *FileNumbers()*, all active files opened by the **FileOpen** function are closed.

When you close files that were opened for **Output** or **Append**, the final buffer of output is written to the operating system buffer for that file. All buffer space associated with the closed file is released.

When the **FileClose** function is executed, the association of a file with its file number ends.

Example

This example uses the **FileClose** function to close a file opened for **Input**.

```
Dim TextLine As String
FileOpen(1, "TESTFILE", OpenMode.Input)   ' Open file.
Do While Not EOF(1)   ' Loop until end of file.
   TextLine = LineInput(1)   ' Read line into variable.
   Debug.WriteLine(TextLine)   ' Print to the Immediate window.
Loop
FileClose(1)   ' Close file.
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

End Statement | FileOpen Function | Reset Function | Stop Statement | File Access with Visual Basic Run-Time Functions| IOException Class

FileCopy Function

Copies a file.

```
Public Sub FileCopy( _
   ByVal Source As String, _
   ByVal Destination As String _
)
```

Parameters

Source
Required. **String** expression that specifies the name of the file to be copied. *Source* may include the directory or folder, and drive, of the source file.

Destination
Required. **String** expression that specifies the target file name. *Destination* may include the directory or folder, and drive, of the destination file.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	52	*Source* or *Destination* is invalid or not speci fied.
IOException	55	File is already open.
FileNotFoundException	53	File does not exist.

Remarks

If you try to use the **FileCopy** function on a currently open file, an error occurs.

Example

This example uses the **FileCopy** function to copy one file to another. For purposes of this example, assume that `SRCFILE` is a file containing some data.

```
Dim SourceFile, DestinationFile As String
SourceFile = "SRCFILE"   ' Define source file name.
DestinationFile = "DESTFILE"   ' Define target file name.
FileCopy(SourceFile, DestinationFile)   ' Copy source to target.
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in MicrosoftVisualBasic.dll)

FileDateTime Function

Returns a **Date** value that indicates the date and time when a file was created or last modified.

```
Public Function FileDateTime(ByVal PathName As String) As DateTime
```

Parameter

PathName
Required. **String** expression that specifies a file name. *PathName* may include the directory or folder, and the drive.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	52	*PathName* is invalid or contains wildcards .
FileNotFoundException	53	Target file does not exist.

Example

This example uses the **FileDateTime** function to determine the date and time a file was created or last modified. The format of the date and time displayed is based on the locale settings of your system.

```
Dim MyStamp As Date
' Assume TESTFILE was last modified on October 12, 2001 at 4:35:47 PM.
' Assume English/U.S. locale settings.
' Returns "10/12/2001 4:35:47 PM".
MyStamp = FileDateTime("C:\TESTFILE.txt")
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

FileGet Function

Reads data from an open disk file into a variable.

```
Public Overloads Sub FileGet( _
   ByVal FileNumber As Integer, _
   ByRef Value As Object, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Public Overloads Sub FileGet( _
   ByVal FileNumber As Integer, _
   ByRef Value As Short, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Public Overloads Sub FileGet( _
   ByVal FileNumber As Integer, _
   ByRef Value As Integer, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Public Overloads Sub FileGet( _
   ByVal FileNumber As Integer, _
   ByRef Value As Single, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Public Overloads Sub FileGet( _
   ByVal FileNumber As Integer, _
   ByRef Value As Double, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Public Overloads Sub FileGet( _
   ByVal FileNumber As Integer, _
   ByRef Value As Decimal, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Public Overloads Sub FileGet( _
   ByVal FileNumber As Integer, _
   ByRef Value As Byte, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Public Overloads Sub FileGet( _
   ByVal FileNumber As Integer, _
   ByRef Value As Boolean, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Public Overloads Sub FileGet( _
   ByVal FileNumber As Integer, _
   ByRef Value As Date, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Public Overloads Sub FileGet( _
   ByVal FileNumber As Integer, _
   ByRef Value As System.Array, _
   Optional RecordNumber As Integer = -1, _
   Optional ArrayIsDynamic as Boolean = False _
)
```

-or-

```
Public Overloads Sub FileGet(
   ByVal FileNumber As Integer, _
   ByRef Value As String, _
   Optional RecordNumber As Integer = -1, _
   Optional StringIsFixedLength as Boolean = False _
)
```

Parameters

FileNumber
Required. Any valid file number.
Value
Required. Valid variable name into which data is read.
RecordNumber
Optional. Record number (**Random** mode files) or byte number (**Binary** mode files) at which reading begins.
ArrayIsDynamic
Optional. Applies only when writing an array. Specifies whether the array is to be treated as dynamic and so whether to write an array descriptor describing the size and bounds of the array.
StringIsFixedLength
Optional. Applies only when writing a string. Specifies whether to write a two-byte descriptor for the string describing the length. The default is **False**.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	63	*RecordNumber* < 1 and not equal to -1 .
IOException	52	*FileNumber* does not exist.
IOException	54	File mode is invalid.

Remarks

FileGet is only valid in **Random** and **Binary** mode.

Data read with **FileGet** is usually written to a file with **FilePut**.

The first record or byte in a file is at position 1, the second record or byte at position 2, and so on. If you omit *RecordNumber*, the next record or byte following the last **FileGet** or **FilePut** function (or pointed to by the last **Seek** function) is read.

> **Security Note** When reading from files, do not make decisions about the contents of a file based on the file name extension. For example, a file named Form1.vb may not be a Visual Basic .NET source file.

For files opened in **Random** mode, the following rules apply:

- If the length of the data being read is less than the length specified in the *RecordLength* clause of the **FileOpen** function, **FileGet** reads subsequent records on record-length boundaries. The space between the end of one record and the beginning of the next record is padded with the existing contents of the file buffer. Because the amount of padding data can't be determined with any certainty, it is generally a good idea to have the record length match the length of the data being read.
- If the variable being read into is a string, by default **FileGet** reads a two-byte descriptor containing the string length and then reads the data that goes into the variable. Therefore, the record length specified by the *RecordLength* clause of the **FileOpen** function must be at least two bytes greater than the actual length of the string. Visual Basic 6 and earlier versions supported fixed-length strings and when put to a file, the length descriptor would not be written. If you wish to read a string without the descriptor, you should pass **True** to the *StringIsFixedLength* parameter, and the string you read into should be the correct length.
- If the variable being read into is an array, then you have a choice as to whether to read a descriptor for the size and dimension of the array. To write the descriptor, set the *ArrayIsDynamic* parameter to **True**. When reading the array, you need to match the way the array was written. If it was written with the descriptor, then you need to read the descriptor. If the descriptor is not used, then the size and bounds of the array passed into **FileGet** will be used to determine what to read.

  The descriptor specifies the rank of the array, the size, and the lower bounds for each rank. Its length equals 2 plus 8 times the number of dimensions, that is, 2 + 8 * *NumberOfDimensions*. The record length specified by the *RecordLength* parameter in the **FileOpen** function must be greater than or equal to the sum of all the bytes required to write the array data and the array descriptor. For example, the following array declaration requires 118 bytes when the array is written to disk.

  ```
  Dim MyArray(4,9) As Integer
  ```

  The 118 bytes are distributed as follows: 18 bytes for the descriptor (2 + 8 * 2), and 100 bytes for the data (5 * 10 * 2).

- If the variable being read into is any other type of variable (not a variable-length string or an object), **FileGet** reads only the variable data. The record length specified by the *RecordLength* clause in the **FileOpen** function must be greater than or equal to the length of the data being read.
- **FileGet** reads elements of structures as if each were being read individually, except that there is no padding between elements. On disk, a dynamic array in a user-defined type (written with **FilePut**) is prefixed by a descriptor whose length equals 2 plus 8 times the number of dimensions, that is, 2 + 8 * *NumberOfDimensions*. The record length specified by the *RecordLength* clause in the **FileOpen** function must be greater than or equal to the sum of all the bytes required to read the individual elements, including any arrays and their descriptors. The **VBFixedString** attribute can be applied to string fields in the structures to indicate the size of string when written to disk.

For files opened in **Binary** mode, all of the **Random** mode rules apply, except:

- The *RecordLength* clause in the **FileOpen** function has no effect. **FileGet** reads all variables from disk contiguously; that is, with no padding between records.
- For any array other than an array in a structure, **FileGet** reads only the data. No descriptor is read.
- **FileGet** reads variable-length strings that aren't elements of structures without expecting the two-byte length descriptor. The number of bytes read equals the number of characters already in the string. For example, the following statements read 11 bytes from file number 1:

  ```
  Dim hellow As New String(" ", 11)
  FileOpen(1, "C:\TESTFILE.txt", OpenMode.Binary)
  FileGet(1, hellow)
  Console.WriteLine(hellow)
  FileClose(1)
  ```

  > **Security Note** Reading from a file with the **FileGet** function requires **Read** access from the

FileIOPermissionAccess enumeration. For more information, see FileIOPermissionAccess Enumeration.

FileGetObject Function

Reads data from an open disk file into a variable.

```
Public Sub FileGetObject( _
   ByVal FileNumber As Integer, _
   ByRef Value As Object, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Overloads Public Sub FileGetObject( _
   ByVal FileNumber As Integer, _
   ByRef Value As Short, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Overloads Public Sub FileGetObject( _
   ByVal FileNumber As Integer, _
   ByRef Value As Integer, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Overloads Public Sub FileGetObject( _
   ByVal FileNumber As Integer, _
   ByRef Value As Single, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Overloads Public Sub FileGetObject( _
   ByVal FileNumber As Integer, _
   ByRef Value As Double, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Overloads Public Sub FileGetObject( _
   ByVal FileNumber As Integer, _
   ByRef Value As Decimal, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```

   ByVal FileNumber As Integer, _
   ByRef Value As Date, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Overloads Public Sub FileGetObject( _
   ByVal FileNumber As Integer, _
   ByRef Value As System.Array, _
   Optional RecordNumber As Integer = -1, _
   Optional ArrayIsDynamic as Boolean = False _
)
```

-or-

```
Overloads Public Sub FileGetObject( _
   ByVal FileNumber As Integer, _
   ByRef Value As String, _
   Optional RecordNumber As Integer = -1, _
   Optional StringIsFixedLength as Boolean = False _
)
```

Parameters

FileNumber
Required. Any valid file number.
Value
Required. Valid variable name into which data is read.
RecordNumber
Optional. Record number (**Random** mode files) or byte number (**Binary** mode files) at which reading begins.
ArrayIsDynamic
Optional. Applies only when writing an array. Specifies whether the array is to be treated as dynamic and so whether to write an array descriptor describing the size and bounds of the array.
StringIsFixedLength
Optional. Applies only when writing a string. Specifies whether to write a two-byte descriptor for the string describing the length. The default is **False**.

Remarks

The **FileGetObject** function is used in place of **FileGet** to avoid ambiguities at compile time if type **Object** is returned rather than another type, such as **Integer**, **Long**, **Short**, and so forth.

If you intend to write out the **Variant** type, **FileGetObject** is required. When in doubt, if you are using an object for the second parameter, it is always safer to use **FilePutObject** and **FileGetObject**.

FileGetObject is only valid in **Random** and **Binary** mode.

Data read with **FileGetObject** is usually written with **FilePutObject**.

The first record or byte in a file is at position 1, the second record or byte is at position 2, and so on. If you omit *RecordNumber*, **FileGetObject** reads the record or byte after the last **FileGetObject** or **FilePutObject** function (or pointed to by the last **Seek** function).

For files opened in **Random** mode, the following rules apply:

- If the length of the data being read is less than the length specified in the *RecordLength* clause of the **FileOpen** function, **FileGetObject** reads subsequent records on record-length boundaries. The space between the end of one record and the beginning of the next record is padded with the existing contents of the file buffer. Because the amount of padding data can't be precisely determined, it is a good idea to have the record length match the length of the data being read.
- If the variable being read into is a string, by default **FileGetObject** reads a two-byte descriptor containing the string length and then reads the data that goes into the variable. Therefore, the record length specified by the *RecordLength* clause of the **FileOpen** function must be at least two bytes greater than the actual length of the string. Visual Basic 6 and earlier versions supported fixed-length strings and when read to a file, the length descriptor would not be written. If you wish to read a string without the descriptor, you should pass **True** to the *StringIsFixedLength* parameter, and the string you read into should be the correct length.
- If the variable being read into is an array, then you can choose to read a descriptor for the size and dimension of the array. To read the descriptor, set the *ArrayIsDynamic* parameter to **True**. When reading the array, you need to match the way the array was written. If it was written with the descriptor, you need to read the descriptor. If the descriptor is not used, the size and bounds of the array passed into **FileGetObject** is used to determine what to read.

  The descriptor specifies the rank of the array, the size, and the lower bounds for each rank. Its length equals 2 plus 8 times the number of dimensions, that is, 2 + 8 * *NumberOfDimensions*. The record length specified by the *RecordLength* parameter in the **FileOpen** function must be greater than or equal to the sum of all the bytes required to write the array data and the array descriptor. For example, the following array declaration requires 118 bytes when the array is written to disk:

  ```
  Dim MyArray(4,9) As Integer
  ```

  The 118 bytes are distributed as follows: 18 bytes for the descriptor (2 + 8 * 2), and 100 bytes for the data (5 * 10 * 2).

- **FileGetObject** reads elements of structures as if each were being read individually, except that there is no padding between elements. On disk, a dynamic array in a user-defined type (written with **FilePutObject**) is prefixed by a descriptor whose length equals 2 plus 8 times the number of dimensions, that is, 2 + 8 * *NumberOfDimensions*. The record length specified by the *RecordLength* clause in the **FileOpen** function must be greater than or equal to the sum of all the bytes required to read the individual elements, including any arrays and their descriptors. The **VBFixedString** attribute can be applied to string fields in the structures to indicate the size of string when written to disk.

For files opened in **Binary** mode, all of the **Random** rules apply, except:

- The *RecordLength* clause in the **FileOpen** function has no effect. **FileGetObject** reads all variables from disk contiguously; that is, with no padding between records.
- For any array other than an array in a structure, **FileGetObject** reads only the data. No descriptor is read.

FileGetObject reads variable-length strings that aren't elements of structures without expecting the two-byte length descriptor. The number of bytes read equals the number of characters already in the string.

> **Security Note** When reading from files, do not make decisions about the contents of a file based on the file name extension. For example, a file named Form1.vb may not be a Visual Basic .NET source file.

Example

The following example reads a record into a test file and then retrieves it.

```
Dim c As String
FileSystem.FileOpen(1, "test.dat", OpenMode.Binary)
FileSystem.FilePutObject(1, "ABCDEF")
FileSystem.Seek(1, 1)
FileSystem.FileGetObject(1, c)
MsgBox(c)
FileSystem.FileClose(1)
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

FilePut Function | FileOpen Function | Seek Function | File Access Types and Functions | FileGet Function

FileLen Function

Returns a **Long** value specifying the length of a file in bytes.

```
Public Function FileLen(ByVal PathName As String) As Long
```

Parameter

PathName
Required. **String** expression that specifies a file. *PathName* may include the directory or folder, and the drive.

Exceptions/Errors

Exception type	Error number	Condition
FileNotFoundException	53	File does not exist.

Remarks

If the specified file is open when the **FileLen** function is called, the value returned represents the size of the file at the time it was opened.

Note To obtain the current length of an open file, use the **LOF** function.

Example

This example uses the **FileLen** function to return the length of a file in bytes. For purposes of this example, assume that `TESTFILE` is a file containing some data.

```
Dim MySize As Long
MySize = FileLen("TESTFILE")   ' Returns file length (bytes).
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in MicrosoftVisualBasic.dll)

See Also

FileDateTime Function | GetAttr Function | LOF Function | FileNotFoundException Class

FileOpen Function

Opens a file for input or output.

```
Public Sub FileOpen( _
   ByVal FileNumber As Integer, _
   ByVal FileName As String, _
   ByVal Mode As OpenMode, _
   Optional ByVal Access As OpenAccess = OpenAccess.Default, _
   Optional ByVal Share As OpenShare = OpenShare.Default, _
   Optional ByVal RecordLength As Integer = -1 _
)
```

Parameters

FileNumber
Required. Any valid file number. Use the **FreeFile** function to obtain the next available file number.
FileName
Required. **String** expression that specifies a file name — may include directory or folder, and drive.
Mode
Required. **Enum** specifying the file mode: **Append**, **Binary**, **Input**, **Output**, or **Random**.
Access
Optional. Keyword specifying the operations permitted on the open file: **Read**, **Write**, or **ReadWrite**. Defaults to **ReadWrite**.
Share
Optional. **Enum** specifying the operations restricted on the open file by other processes: **Shared**, **Lock Read**, **Lock Write**, and **Lock Read Write**. Defaults to **Lock Read Write**.
RecordLength
Optional. Number less than or equal to 32,767 (bytes). For files opened for random access, this value is the record length. For sequential files, this value is the number of characters buffered.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	Invalid **Access, Share,** or **Mode.**
ArgumentException	5	**WriteOnly** file is opened for **Input.**
ArgumentException	5	**ReadOnly** file is opened for **Output.**
ArgumentException	5	**ReadOnly** file is opened for **Append.**
ArgumentException	5	Record length is negative (and not equal to -1).
IOException	52	*FileNumber* is invalid (<-1 or >255), or *File Number* is already in use.
IOException	55	*FileName* is already open, or *FileName* is in valid.

Remarks

You must open a file before any I/O operation can be performed on it. **FileOpen** allocates a buffer for I/O to the file and determines the mode of access to use with the buffer.

> **Security Note** When writing to files, an application may need to create a file if the file to which it is trying to write does not exist. To do so, it needs permission for the directory in which the file is to be created. However, if the file specified by *FileName* does exist, the application only needs **Write** permission to the file itself. Wherever possible, it is more secure to create the file during deployment and only grant **Write** permission to that file, rather than to the entire directory. It is also more secure to write data to user directories than to the root directory or the Program Files directory.

The channel to open can be found using the **FreeFile()** function.

> **Security Note** The **FileOpen** function requires **Read** access from the **FileIOPermissionAccess** enumeration, which may affect its execution in partial trust situations. For more information, see FileIOPermissionAccess Enumeration and

Requesting Permissions.

Example

This example illustrates various uses of the **FileOpen** function to enable input and output to a file.

The following code opens the file `TESTFILE` in **Input** mode.

```
FileOpen(1, "TESTFILE", OpenMode.Input)
' Close before reopening in another mode.
FileClose(1)
```

This example opens the file in **Binary** mode for writing operations only.

```
FileOpen(1, "TESTFILE", OpenMode.Binary,OpenAccess.Write)
' Close before reopening in another mode.
FileClose(1)
```

The following example opens the file in **Random** mode. The file contains records of the structure `Person`.

```
Structure Person
   <VBFixedString(30)> Dim Name As String
   Dim ID As Integer
End Structure
' Count 30 for the string, plus 4 for the integer.
FileOpen(1, "TESTFILE", OpenMode.Random, , , 34)
' Close before reopening in another mode.
FileClose(1)
```

This code example opens the file in **Output** mode; any process can read or write to file.

```
FileOpen(1, "TESTFILE", OpenMode.Output, OpenShare.Shared)
' Close before reopening in another mode.
FileClose(1)
```

This code example opens the file in **Binary** mode for reading; other processes can't read file.

```
FileOpen(1, "TESTFILE", OpenMode.Binary, OpenAccess.Read, _
   OpenShare.LockRead)
```

FilePut Function

Writes data from a variable to a disk file.

```
Public Overloads Sub FilePut( _
   FileNumber As Integer, _
   Value As Short, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Public Overloads Sub FilePut( _
   FileNumber As Integer, _
   Value As Integer, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Public Overloads Sub FilePut( _
   FileNumber As Integer, _
   Value As Single, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Public Overloads Sub FilePut( _
   FileNumber As Integer, _
   Value As Double, _
   RecordNumber As Integer = -1 _
)
```

-or-

```
Public Overloads Sub FilePut( _
   FileNumber As Integer, _
   Value As Decimal, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Public Overloads Sub FilePut( _
   FileNumber As Integer, _
   Value As Byte, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Public Overloads Sub FilePut( _
   FileNumber As Integer, _
   Value As Boolean, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Public Overloads Sub FilePut( _
   FileNumber As Integer, _
   Value As Date, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Public Overloads Sub FilePut( _
   FileNumber As Integer, _
   Value As System.Array, _
   Optional RecordNumber As Integer = -1, _
   Optional ArrayIsDynamic As Boolean = False _
)
```

-or-

```
Public Overloads Sub FilePut (
   FileNumber As Integer,
   Value As String, _
   Optional RecordNumber As Integer = -1,
   Optional StringIsFixedLength As Boolean = False
)
```

Parameters

FileNumber
Required. Any valid file number.
Value
Required. Valid variable name containing data written to disk.
RecordNumber
Optional. Record number (**Random** mode files) or byte number (**Binary** mode files) at which writing begins.
ArrayIsDynamic
Optional. Applies only when writing an array. Specifies whether the array is to be treated as dynamic, and whether to write an array descriptor for the string describing the length.
StringIsFixedLength
Optional. Applies only when writing a string. Specifies whether to write a two-byte string length descriptor for the string to the file. The default is **False**.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	63	*RecordNumber* < 1 and not equal to -1 .
IOException	52	*FileNumber* does not exist.
IOException	54	File mode is invalid.

Remarks

FilePut is only valid in **Random** and **Binary** mode.

Data written with **FilePut** is usually read from a file with **FileGet**.

The first record or byte in a file is at position 1, the second record or byte at position 2, and so on. If you omit *RecordNumber*, the next record or byte after the last **FileGet** or **FilePut** function or pointed to by the last **Seek** function is written.

The *StringIsFixedLength* argument controls whether the function interprets strings as variable or fixed length. **FilePut** does not write the length descriptor when the argument is **True**. If you use *StringIsFixedLength* = **True** with **FilePut**, you will need to do the same with **FileGet**, and also make sure the string is initialized to the length expected.

For files opened in **Random** mode, the following rules apply:

- If the length of the data being written is less than the length specified in the *RecordLength* clause of the **FileOpen** function, **FilePut** writes subsequent records on record-length boundaries. The space between the end of one record and the beginning of the next record is padded with the existing contents of the file buffer. Because the amount of padding data can't be determined with any certainty, it is generally a good idea to have the record length match the length of the data being written. If the length of the data being written is greater than the length specified in the *RecordLength* clause of the **FileOpen** function, an exception will be thrown.
- If the variable being written is a string, **FilePut** writes a two-byte descriptor containing the string length, and then writes the data that goes into the variable. Therefore, the record length specified by the *RecordLength* clause in the **FileOpen** function must be at least two bytes greater than the actual length of the string.
- If the variable being written is an object containing a numeric type, **FilePut** writes two bytes identifying the **VarType** of the object and then writes the variable. For example, when writing an object containing an integer, **FilePut** writes six bytes: two bytes identifying the object as **VarType(**3**)** (**Integer**) and four bytes containing the data. The record length specified by the *RecordLength* parameter in the **FileOpen** function must be at least two bytes greater than the actual number of bytes required to store the variable.
- If the variable being written is an object containing a string, **FilePut** writes a two byte descriptor identifying the **VarType(**8**)** of the object, a two-byte descriptor indicating the length of the string, and then writes the string data. The record length specified by the *RecordLength* parameter in the **FileOpen** function must be at least four bytes greater than the actual length of the string. If you wish to put a string without the descriptor, then you should pass **True** to the *StringIsFixedLength* parameter, and the string you read into should be the correct length.
- If the variable being written is an array, then you have a choice as to whether or not to write a descriptor for the size and dimensions of the array. Visual Basic 6 and earlier versions would write the file descriptor for a dynamic array, but not for a fixed-size array. Visual Basic .NET defaults to not writing the descriptor. To write the descriptor, set the *ArrayIsDynamic* parameter to **True**. When writing the array, you need to match the way the array will be read; if it will be read with the descriptor, then you need to write the descriptor. The descriptor specifies the rank of the array, the size, and the lower bounds for each rank. Its length equals 2 plus 8 times the number of dimensions, that is, 2 + 8 * *NumberOfDimensions*. The record length specified by the *RecordLength* clause in the **FileOpen** function must be greater than or equal to the sum of all the bytes required to write the array data and the array descriptor. For example, the following array declaration requires 118 bytes when the array is written to disk.

  ```
  Dim MyArray(4,9) As Integer
  ```

- If the variable being written is any other type of variable (not a variable-length string or an object), **FilePut** writes only the variable data. The record length specified by the *RecordLength* clause in the **FileOpen** function must be greater than or equal to the length of the data being written.
- **FilePut** writes elements of structures as if each were written individually, except there is no padding between elements. The **VBFixedString** attribute can be applied to string fields in the structures to indicate the size of the string when written to disk.

For files opened in **Binary** mode, all of the **Random** mode rules apply, except:

- The *RecordLength* clause in the **FileOpen** function has no effect. **FilePut** writes all variables to disk contiguously; that is, with no padding between records.
- For any array other than an array in a structure, **FilePut** writes only the data. No descriptor is written.
- **FilePut** writes variable-length strings that are not elements of structures without the two-byte length descriptor. The number of bytes written equals the number of characters in the string. For example, the following statements write 11 bytes to file number 1:

  ```
  Dim hellow As String = "Hello World"
  FilePut(1,hellow)
  ```

- Writing to a file with the **FilePut** function requires **Write** access from the **FileIOPermissionAccess** enumeration. For more information, see FileIOPermissionAccess Enumeration.

Example

This example uses the **FilePut** function to write data to a file. Five records of the structure `Person` are written to the file.

```
Structure Person
   Public ID As Integer
```

```
    Public Name As String
End Structure

Sub WriteData()
    Dim MyRecord As Person
    Dim recordNumber As Integer
'     Open file for random access.
    FileOpen(1, "C:\TESTFILE.txt", OpenMode.Binary)
    For recordNumber = 1 To 5    ' Loop 5 times.
        MyRecord.ID = recordNumber    ' Define ID.
        MyRecord.Name = "My Name" & recordNumber    ' Create a string.
        FilePut(1, MyRecord)    ' Write record to file.
    Next recordNumber
    FileClose(1)
End Sub
```

FilePutObject Function

Writes data from a variable to a disk file.

```
Public Sub FilePutObject( _
   FileNumber As Integer, _
   Value As Object, _
   RecordNumber As Integer = -1 _
)
```

-or-

```
Overloads Public Sub FilePutObject( _
   FileNumber As Integer, _
   Value As Short, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Overloads Public Sub FilePutObject( _
   FileNumber As Integer, _
   Value As Integer, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Overloads Public Sub FilePutObject( _
   FileNumber As Integer, _
   Value As Single, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Overloads Public Sub FilePutObject( _
   FileNumber As Integer, _
   Value As Double, _
   RecordNumber As Integer = -1 _
)
```

-or-

```
Overloads Public Sub FilePutObject( _
   FileNumber As Integer, _
   Value As Decimal, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Overloads Public Sub FilePutObject( _
   FileNumber As Integer, _
   Value As Byte, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Overloads Public Sub FilePutObject( _
   FileNumber As Integer, _
   Value As Boolean, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Overloads Public Sub FilePutObject( _
   FileNumber As Integer, _
   Value As Date, _
   Optional RecordNumber As Integer = -1 _
)
```

-or-

```
Overloads Public Sub FilePutObject( _
   FileNumber As Integer, _
   Value As System.Array, _
   Optional RecordNumber As Integer = -1, _
   Optional ArrayIsDynamic As Boolean = False _
)
```

-or-

```
Overloads Public Sub FilePutObject( _
   FileNumber As Integer, _
   Value As String, _
   Optional RecordNumber As Integer = -1, _
   Optional StringIsFixedLength as Boolean = False _
)
```

Parameters

FileNumber
Required. Any valid file number.
Value
Required. Valid variable name containing data written to disk.
RecordNumber
Optional. Record number (**Random** mode files) or byte number (**Binary** mode files) at which writing begins.
ArrayIsDynamic
Optional. Applies only when writing an array. Specifies whether the array is to be treated as dynamic, and whether to write an array descriptor for the string describing the length.
StringIsFixedLength
Optional. Applies only when writing a string. Specifies whether to write a descriptor for the string describing the length. The default is **False**.

Remarks

The **FilePutObject** function is used in place of **FilePut** to avoid ambiguities at compile time if type **Object** is passed rather than another type, such as **Integer**, **Long**, **Short**, and so forth.

FilePutObject writes and reads descriptors that describe the object. If you intend to write out the **Variant** type, **FilePutObject** is required. When in doubt, if you are using an object for the second parameter, it is always safer to use **FilePutObject** and **FileGetObject**.

FilePutObject is only valid in **Random** and **Binary** mode.

Data written with **FilePutObject** is usually read from a file with **FileGetObject**.

The first record or byte in a file is at position 1, the second record or byte is at position 2, and so on. If you omit *RecordNumber*, **FilePutObject** writes the next record or byte after the last **FileGetObject** or **FilePutObject** function (or the record or byte

pointed to by the last **Seek** function).

The *StringIsFixedLength* argument controls whether the function interprets strings as variable or fixed length. **FilePutObject** does not write the length descriptor when the argument is **True**. If you use *StringIsFixedLength* = **True** with **FilePutObject**, you need to do the same with **FileGetObject**, and must also make sure that the string is initialized to the length expected.

For files opened in **Random** mode, the following rules apply:

- If the length of the data being written is less than the length specified in the *RecordLength* clause of the **FileOpen** function, **FilePutObject** writes subsequent records on record-length boundaries. The space between the end of one record and the beginning of the next record is padded with the existing contents of the file buffer. Because the amount of padding data can't be precisely determined, it is generally a good idea to have the record length match the length of the data being written. If the length of the data being written is greater than the length specified in the *RecordLength* clause of the **FileOpen** function, an exception is thrown.
- If the variable being written is an object containing a numeric type, **FilePutObject** writes two bytes identifying the **VarType** of the object and then writes the variable. For example, when writing an object containing an integer, **FilePutObject** writes six bytes: two bytes identifying the object as **VarType(**3**)** (**Integer**) and four bytes containing the data. The record length specified by the *RecordLength* parameter in the **FileOpen** function must be at least two bytes greater than the actual number of bytes required to store the variable.
- If the variable being written is an object containing a string, **FilePutObject** writes a two-byte descriptor identifying the **VarType(**8**)** of the object, a two-byte descriptor indicating the length of the string, and then writes the string data. The record length specified by the *RecordLength* parameter in the **FileOpen** function must be at least four bytes greater than the actual length of the string. If you wish to put a string without the descriptor, then you should pass **True** to the *StringIsFixedLength* parameter, and the string you read into should be the correct length.
- If the variable being written is an array, you can choose to write a descriptor for the size and dimensions of the array. Visual Basic 6 and earlier versions would write the file descriptor for a dynamic array, but not for a fixed-size array; Visual Basic .NET defaults to not writing the descriptor. To write the descriptor, set the *ArrayIsDynamic* parameter to **True**. When writing the array, you need to match the way the array is read; if it is read with the descriptor, you need to write the descriptor. The descriptor specifies the rank of the array, the size, and the lower bounds for each rank. Its length equals 2 plus 8 times the number of dimensions, that is, 2 + 8 * *NumberOfDimensions*. The record length specified by the *RecordLength* clause in the **FileOpen** function must be greater than or equal to the sum of all the bytes required to write the array data and the array descriptor.

For files opened in **Binary** mode, all of the **Random** mode rules apply, except:

- The *RecordLength* clause in the **FileOpen** function has no effect. **FilePutObject** writes all variables to disk contiguously, that is, with no padding between records.

Example

This example uses the **FilePutObject** function to write a string to a file.

```
Sub WriteData()
    Dim text As String = "test"
    FileOpen(1, "test.bin", OpenMode.Binary)
    FilePutObject(1, text)
    FileClose(1)
End Sub
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

FileWidth Function

Assigns an output line width to a file opened using the **FileOpen** function.

```
Public Sub FileWidth( _
   FileNumber As Integer, _
   RecordWidth As Integer _
)
```

Parameters

FileNumber
Required. Any valid file number.

RecordWidth
Required. Numeric expression in the range 0–255, inclusive, which indicates how many characters appear on a line before a new line is started. If *RecordWidth* equals 0, there is no limit to the length of a line. The default value for *RecordWidth* is 0.

Exceptions/Errors

Exception type	Error number	Condition
IOException	52	*FileNumber* does not exist.
IOException	54	File mode is invalid.

Example

This example uses the **FileWidth** function to set the output line width for a file.

```
Dim i As Integer
FileOpen(1, "TESTFILE", OpenMode.Output) ' Open file for output.
FileWidth(1, 5)   ' Set output line width to 5.
For i = 0 To 9   ' Loop 10 times.
   Print(1, Chr(48 + I))   ' Prints five characters per line.
Next
FileClose(1)   ' Close file.
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

FileOpen Function | Print, PrintLine Functions | IOException Class

Filter Function

Returns a zero-based array containing a subset of a **String** array based on specified filter criteria.

```
Function Filter(
   ByVal Source() As { Object | String },
   ByVal Match As String,
   Optional ByVal Include As Boolean = True,
   Optional ByVal Compare As CompareMethod = CompareMethod.Binary
)  As String()
```

Parameters

Source
Required. One-dimensional array of strings to be searched.
Match
Required. String to search for.
Include
Optional. **Boolean** value indicating whether to return substrings that include or exclude *Match*. If *Include* is **True**, the **Filter** function returns the subset of the array that contains *Match* as a substring. If *Include* is **False**, the **Filter** function returns the subset of the array that does not contain *Match* as a substring.
Compare
Optional. Numeric value indicating the kind of string comparison to use. See Settings for values.

Settings

The *Compare* argument can have the following values:

Constant	Description
CompareMethod.Binary	Performs a binary comparison
CompareMethod.Text	Performs a textual comparison

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Source* is **Nothing** or is not a one-dimensional array.

Remarks

If no matches of *Match* are found within *Source*, the **Filter** function returns an empty array. An error occurs if *Source* is set to **Nothing** or is not a one-dimensional array.

The array returned by the **Filter** function contains only enough elements to contain the number of matched items.

Example

This example demonstrates the use of the **Filter** function.

```
Dim myStrings(2) As String
MyStrings(0) = "This"
MyStrings(1) = "Is"
MyStrings(2) = "It"
' Returns ["This", "Is"].
Dim subStrings() As String = Filter(myStrings, "is", True, _
   CompareMethod.Text)
' Returns ["This"].
Dim subStrings() As String = Filter(myStrings, "is", True, _
   CompareMethod.Binary)
' Returns ["Is", "It"].
Dim subStrings() As String = Filter(myStrings, "is", False, _
```

```
    CompareMethod.Binary)
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Replace Function | ArgumentException

Int, Fix Functions

Return the integer portion of a number.

```
Public Shared Function Int(ByVal number As { Double | Integer | Long | Object | Short | Singl
e | Decimal }) As { Double | Integer | Long | Object | Short | Single | Decimal }
Public Shared Function Fix(ByVal number As { Double | Integer | Long | Object | Short | Singl
e | Decimal }) As { Double | Integer | Long | Object | Short | Single | Decimal }
```

Parameter

number
Required. A number of type **Double** or any valid numeric expression. If *number* contains Nothing, **Nothing** is returned.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentNullException	5	*Number* is not specified.
ArgumentException	5	*Number* is not a numeric type .

Remarks

Both the **Int** and **Fix** functions remove the fractional part of *number* and return the resulting integer value.

The difference between **Int** and **Fix** functions is that if *number* is negative, **Int** returns the first negative integer less than or equal to *number*, whereas **Fix** returns the first negative integer greater than or equal to *number*. For example, **Int** converts -8.4 to -9, and **Fix** converts -8.4 to -8.

`Fix(number)` is equivalent to `Sign(number) * Int(Abs(number))`.

Example

This example illustrates how the **Int** and **Fix** functions return integer portions of numbers. In the case of a negative number argument, the **Int** function returns the first negative integer less than or equal to the number; the **Fix** function returns the first negative integer greater than or equal to the number. The following example requires you to specify **Option Strict Off** because implicit conversions from type **Double** to type **Integer** are not allowed under **Option Strict On**:

```
Option Strict Off
' Code will not function unless placed within a Sub or Function
Dim MyNumber As Integer
MyNumber = Int(99.8)   ' Returns 99.
MyNumber = Fix(99.8)   ' Returns 99.

MyNumber = Int(-99.8)   ' Returns -100.
MyNumber = Fix(-99.8)   ' Returns -99.

MyNumber = Int(-99.2)   ' Returns -100.
MyNumber = Fix(-99.2)   ' Returns -99.
```

You can use the **CInt** function to explicitly convert other data types to type **Integer** with **Option Strict Off**. However, **Cint** rounds to the nearest integer instead of truncating the fractional part of numbers. For example:

```
MyNumber = CInt(99.8)    ' Returns 100.
MyNumber = CInt(-99.8)   ' Returns -100.
MyNumber = CInt(-99.2)   ' Returns -99.
```

You can use the **CInt** function on the result of a call to **Fix** or **Int** to perform explicit conversion to integer without rounding. For example:

```
MyNumber = CInt(Fix(99.8))   ' Returns 99.
MyNumber = CInt(Int(99.8))   ' Returns 99.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Conversion

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

CInt Function | Integer Data Type | Math Summary | Math Functions | ArgumentNullException Class

Format Function

Returns a string formatted according to instructions contained in a format **String** expression.

```
Public Shared Function Format( _
   ByVal Expression As Object, _
   Optional ByVal Style As String = "" _
) As String
```

Parameters

Expression
Required. Any valid expression.
Style
Optional. A valid named or user-defined format **String** expression.

Settings

For information on how to create the *Style* argument, see the appropriate topic listed below:

To format	Do this
Numbers	Use predefined numeric formats or create user-defined numeric formats.
Dates and times	Use predefined date/time formats or create user-defined date/time formats.
Date and time serial numbers	Use date and time formats or numeric formats.

If you try to format a number without specifying *Style*, the **Format** function provides functionality similar to the **Str** function, although it is internationally aware. However, positive numbers formatted as strings using the **Format** function don't include a leading space reserved for the sign of the value; those converted using the **Str** function retain the leading space.

Remarks

If you are formatting a nonlocalized numeric string, you should use a user-defined numeric format to ensure that you get the look you want.

The **String.Format** method also provides similar functionality.

Example

This example shows various uses of the **Format** function to format values using both **String** formats and user-defined formats. For the date separator (**/**), time separator (**:**), and the AM/PM indicators (**t** and **tt**), the actual formatted output displayed by your system depends on the locale settings the code is using. When times and dates are displayed in the development environment, the short time format and short date format of the code locale are used.

```
Dim MyDateTime As Date = #1/27/2001 5:04:23 PM#
Dim MyStr As String
' Returns current system time in the system-defined long time format.
MyStr = Format(Now(), "Long Time")
' Returns current system date in the system-defined long date format.
MyStr = Format(Now(), "Long Date")
' Also returns current system date in the system-defined long date
' format, using the single letter code for the format.
MyStr = Format(Now(), "D")
' Returns the value of MyDateTime in user-defined date/time formats.
MyStr = Format(MyDateTime, "h:m:s")   ' Returns "5:4:23".
MyStr = Format(MyDateTime, "hh:mm:ss tt")   ' Returns "05:04:23 PM".
MyStr = Format(MyDateTime, "dddd, MMM d yyyy")   ' Returns "Saturday,
   ' Jan 27 2001".
MyStr = Format(MyDateTime, "HH:mm:ss")   ' Returns "17:04:23"
MyStr = Format(23)   ' Returns "23".
' User-defined numeric formats.
MyStr = Format(5459.4, "##,##0.00")   ' Returns "5,459.40".
MyStr = Format(334.9, "###0.00")   ' Returns "334.90".
```

```
MyStr = Format(5, "0.00%")   ' Returns "500.00%".
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Different Formats for Different Numeric Values (Format Function) | Predefined Date/Time Formats (Format Function) | Predefined Numeric Formats (Format Function) | Str Function | Type Conversion Functions | User-Defined Date/Time Formats (Format Function) | User-Defined Numeric Formats (Format Function) | String.Format Method

Different Formats for Different Numeric Values (Format Function)

A user-defined format expression for numbers can have from one to three sections separated by semicolons. If the style argument of the **Format** function contains one of the Predefined Numeric Formats, only one section is allowed.

If you use	This is the result
One section only	The format expression applies to all values.
Two sections	The first section applies to positive values and zeros; the second applies to negative values.
Three sections	The first section applies to positive values, the second applies to negative values, and the third applies to zeros.

The following example has two sections: the first defines the format for positive values and zeros; the second section defines the format for negative values. Since the *Style* argument of the **Format** function takes a string, it is enclosed by quotation marks.

```
"$#,##0;($#,##0)"
```

If you include semicolons with nothing between them, the missing section is printed using the format of the positive value. For example, the following format displays positive and negative values using the format in the first section and displays `Zero` if the value is zero.

```
"$#,##0;;\Z\e\r\o"
```

Requirements

Format Function

Predefined Numeric Formats (Format Function)

The following table identifies the predefined numeric format names. These may be used by name as the style argument for the **Format** function:

Format name	Description
General Number, **G**, or **g**	Displays number with no thousand separator.
Currency, **C**, or **c**	Displays number with thousand separator, if appropriate; display two digits to the right of the decimal separator. Output is based on system locale settings.
Fixed, **F**, or **f**	Displays at least one digit to the left and two digits to the right of the decimal separator.
Standard, **N**, or **n**	Displays number with thousand separator, at least one digit to the left and two digits to the right of the decimal separator.
Percent	Displays number multiplied by 100 with a percent sign (%) appended immediately to the right; always displays two digits to the right of the decimal separator.
P, or **p**	Displays number with thousandths separator multiplied by 100 with a percent sign (%) appended to the right and separated by a single space; always displays two digits to the right of the decimal separator.
Scientific	Uses standard scientific notation, providing two significant digits.
E, or **e**	Uses standard scientific notation, providing six significant digits.
D, or **d**	Displays number as a string that contains the value of the number in Decimal (base 10) format. This option is supported for integral types **(Byte**, **Short**, **Integer**, **Long**) only.
X, or **x**	Displays number as a string that contains the value of the number in Hexadecimal (base 16) format. This option is supported for integral types (**Byte**, **Short**, **Integer**, **Long**) only.
Yes/No	Displays `No` if number is 0; otherwise, displays `Yes`.
True/False	Displays `False` if number is 0; otherwise, displays `True`.
On/Off	Displays `Off` if number is 0; otherwise, displays `On`.

Smart Device Developer Notes

The **Yes/No**, **True/False**, and **On/Off** formats are not supported.

Requirements

Format Function | Predefined Date/Time Formats (Format Function) | User-Defined Numeric Formats (Format Function)

Predefined Date/Time Formats (Format Function)

The following table identifies the predefined date and time format names. These may be used by name as the style argument for the **Format** function:

Format Name	Description
General Date, or **G**	Displays a date and/or time. For real numbers, display a date and time; for example, `4/3/93 05:34 PM`.If there is no fractional part, display only a date, for example, `4/3/93`. If there is no integer part, display time only, for example, `05:34 PM`. Date display is determined by your system's **LocaleID** value.
Long Date, or **D**	Displays a date according to your locale's long date format.
Medium Date	Displays a date using the medium date format appropriate for the language version of the host application.
Short Date, or **d**	Displays a date using your locale's short date format.
Long Time, or **T**	Displays a time using your locale's long time format; includes hours, minutes, seconds.
Medium Time	Displays time in 12-hour format using hours and minutes and the AM/PM designator.
Short Time, or **t**	Displays a time using the 24-hour format, for example, `17:45`.
f	Displays the long date and short time according to your locale's format.
F	Displays the long date and long time according to your locale's format.
g	Displays the short date and short time according to your locale's format.
M, **m**	Displays the month and the day of a date.
R, **r**	Formats the date and time as Greenwich Mean Time (GMT)
s	Formats the date and time as a sortable index.
u	Formats the date and time as a GMT sortable index.
U	Formats the date and time with the long date and long time as GMT.
Y, y	Formats the date as the year and month.

Format Function | Predefined Numeric Formats (Format Function) | User-Defined Date/Time Formats (Format Function)

User-Defined Date/Time Formats (Format Function)

The following table shows characters you can use to create user-defined date/time formats. Unlike in previous versions of Visual Basic, these format characters are case-sensitive

Character	Description
(**:**)	Time separator. In some locales, other characters may be used to represent the time separator. The time separator separates hours, minutes, and seconds when time values are formatted. The actual character used as the time separator in formatted output is determined by your system's **LocaleID** value.
(**/**)	Date separator. In some locales, other characters may be used to represent the date separator. The date separator separates the day, month, and year when date values are formatted. The actual character used as the date separator in formatted output is determined by your locale.
(**%**)	Used to indicate that the following character should be read as a single-letter format without regard to any trailing letters. Also used to indicate that a single-letter format is read as a user-defined format. See below for further details
d	Displays the day as a number without a leading zero (for example, `1`). Use **%d** if this is the only character in your user-defined numeric format.
dd	Displays the day as a number with a leading zero (for example, `01`).
ddd	Displays the day as an abbreviation (for example, `Sun`).
dddd	Displays the day as a full name (for example, `Sunday`).
M	Displays the month as a number without a leading zero (for example, January is represented as `1`). Use **%M** if this is the only character in your user-defined numeric format.
MM	Displays the month as a number with a leading zero (for example, `01/12/01`).
MMM	Displays the month as an abbreviation (for example, `Jan`).
MMMM	Displays the month as a full month name (for example, `January`).
gg	Displays the period/era string (for example, `A.D.`)
h	Displays the hour as a number without leading zeros using the 12-hour clock (for example, `1:15:15 PM`). Use **%h** if this is the only character in your user-defined numeric format.
hh	Displays the hour as a number with leading zeros using the 12-hour clock (for example, `01:15:15 PM`).
H	Displays the hour as a number without leading zeros using the 24-hour clock (for example, `1:15:15`). Use **%H** if this is the only character in your user-defined numeric format.
HH	Displays the hour as a number with leading zeros using the 24-hour clock (for example, `01:15:15`).
m	Displays the minute as a number without leading zeros (for example, `12:1:15`). Use **%m** if this is the only character in your user-defined numeric format.
mm	Displays the minute as a number with leading zeros (for example, `12:01:15`).
s	Displays the second as a number without leading zeros (for example, `12:15:5`). Use **%s** if this is the only character in your user-defined numeric format.
ss	Displays the second as a number with leading zeros (for example, `12:15:05`).
F	Displays fractions of seconds. For example **ff** will display hundredths of seconds, whereas **ffff** will display ten-thousandths of seconds. You may use up to seven **f** symbols in your user-defined format. Use **%f** if this is the only character in your user-defined numeric format.
T	Uses the 12-hour clock and displays an uppercase `A` for any hour before noon; displays an uppercase `P` for any hour between noon and 11:59 P.M. Use **%t** if this is the only character in your user-defined numeric format.
tt	Uses the 12-hour clock and displays an uppercase `AM` with any hour before noon; displays an uppercase `PM` with any hour between noon and 11:59 P.M.
y	Displays the year number (0-9) without leading zeros. Use **%y** if this is the only character in your user-defined numeric format.
yy	Displays the year in two-digit numeric format with a leading zero, if applicable.
yyy	Displays the year in four digit numeric format.
yyyy	Displays the year in four digit numeric format.
z	Displays the timezone offset without a leading zero (for example, `-8`). Use **%z** if this is the only character in your user-defined numeric format.
zz	Displays the timezone offset with a leading zero (for example, `-08`)
zzz	Displays the full timezone offset (for example, `-08:00`)

Example

The following are examples of user-defined date and time formats for `December 7, 1958, 8:50 PM, 35 seconds`:

Format	Displays
M/d/yy	12/7/58
d-MMM	7-Dec
d-MMMM-yy	7-December-58
d MMMM	7 December
MMMM yy	December 58
hh:mm tt	08:50 PM
h:mm:ss t	8:50:35 P
H:mm	20:50
H:mm:ss	20:50:35
M/d/yyyy H:mm	12/7/1958 20:50

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Format Function | Predefined Date/Time Formats (Format Function) | User-Defined Numeric Formats (Format Function)

User-Defined Numeric Formats (Format Function)

The following table identifies characters you can use to create user-defined number formats. These may be used to build the style argument for the **Format** function:

Character	Description
None	Displays the number with no formatting.
(**0**)	Digit placeholder. Displays a digit or a zero. If the expression has a digit in the position where the zero appears in the format string, display it; otherwise, displays a zero in that position. If the number has fewer digits than there are zeros (on either side of the decimal) in the format expression, displays leading or trailing zeros. If the number has more digits to the right of the decimal separator than there are zeros to the right of the decimal separator in the format expression, rounds the number to as many decimal places as there are zeros. If the number has more digits to the left of the decimal separator than there are zeros to the left of the decimal separator in the format expression, displays the extra digits without modification.
(**#**)	Digit placeholder. Displays a digit or nothing. If the expression has a digit in the position where the **#** character appears in the format string, displays it; otherwise, displays nothing in that position. This symbol works like the **0** digit placeholder, except that leading and trailing zeros aren't displayed if the number has fewer digits than there are **#** characters on either side of the decimal separator in the format expression.
(**.**)	Decimal placeholder. The decimal placeholder determines how many digits are displayed to the left and right of the decimal separator. If the format expression contains only **#** characters to the left of this symbol; numbers smaller than 1 begin with a decimal separator. To display a leading zero displayed with fractional numbers, use zero as the first digit placeholder to the left of the decimal separator. In some locales, a comma is used as the decimal separator. The actual character used as a decimal placeholder in the formatted output depends on the number format recognized by your system. Thus, You should use the period as the decimal placeholder in your formats even if you are in a locale that uses a comma as a decimal placeholder. The formatted string will appear in the format correct for the locale.
(**%**)	Percent placeholder. Multiplies the expression by 100. The percent character (**%**) is inserted in the position where it appears in the format string.
(**,**)	Thousand separator. The thousand separator separates thousands from hundreds within a number that has four or more places to the left of the decimal separator. Standard use of the thousand separator is specified if the format contains a thousand separator surrounded by digit placeholders (**0** or **#**). A thousand separator immediately to the left of the decimal separator (whether or not a decimal is specified) or as the rightmost character in the string means "scale the number by dividing it by 1,000, rounding as needed." For example, you can use the format string `"##0,."` to represent 100 million as 100,000. Numbers smaller than 1,000 but greater or equal to 500 are displayed as `1`, and numbers smaller than 500 are displayed as `0`. Two adjacent thousand separators in this position scale by a factor of 1 million, and an additional factor of 1,000 for each additional separator. Multiple separators in any position other than immediately to the left of the decimal separator or the rightmost position in the string are treated simply as specifying the use of a thousand separator. In some locales, a period is used as a thousand separator. The actual character used as the thousand separator in the formatted output depends on the Number Format recognized by your system. Thus, You should use the comma as the thousand separator in your formats even if you are in a locale that uses a period as a thousand separator. The formatted string will appear in the format correct for the locale.
(**:**)	Time separator. In some locales, other characters may be used to represent the time separator. The time separator separates hours, minutes, and seconds when time values are formatted. The actual character used as the time separator in formatted output is determined by your system settings.
(**/**)	Date separator. In some locales, other characters may be used to represent the date separator. The date separator separates the day, month, and year when date values are formatted. The actual character used as the date separator in formatted output is determined by your system settings.

(**E- E+ e- e+**)	Scientific format. If the format expression contains at least one digit placeholder (**0** or **#**) to the left of **E-**, **E+**, **e-**, or **e+**, the number is displayed in scientific format and `E` or `e` is inserted between the number and its exponent. The number of digit placeholders to the left determines the number of digits in the exponent. Use **E-** or **e-** to place a minus sign next to negative exponents. Use **E+** or **e+** to place a minus sign next to negative exponents and a plus sign next to positive exponents. You must also include digit placeholders to the right of this symbol to get correct formatting.
- + $ ( )	Literal characters. These characters are displayed exactly as typed in the format string. To display a character other than one of those listed, precede it with a backslash (****) or enclose it in double quotation marks (" ").
(****)	Displays the next character in the format string. To display a character that has special meaning as a literal character, precede it with a backslash (****). The backslash itself isn't displayed. Using a backslash is the same as enclosing the next character in double quotation marks. To display a backslash, use two backslashes (****). Examples of characters that can't be displayed as literal characters are the date-formatting and time-formatting characters (**a**, **c**, **d**, **h**, **m**, **n**, **p**, **q**, **s**, **t**, **w**, **y**, **/**, and **:**), the numeric-formatting characters (**#**, **0**, **%**, **E**, **e**, comma, and period), and the string-formatting characters (**@**, **&**, **<**, **>**, and **!**).
(**"ABC"**)	Displays the string inside the double quotation marks (" "). To include a string in the style argument from within code, you must use **Chr(34)** to enclose the text (**34** is the character code for a quotation mark (").

Example

The following table contains some sample format expressions for numbers. (These examples all assume that your system's locale setting is English-U.S.) The first column contains the format strings for the *Style* argument of the **Format** function; the other columns contain the resulting output if the formatted data has the value given in the column headings.

Format (*Style*)	**"5" formatted as**	**"-5" formatted as**	**"0.5" formatted as**
`Zero-length string ("")`	`5`	`-5`	`0.5`
`0`	`5`	`-5`	`1`
`0.00`	`5.00`	`-5.00`	`0.50`
`#,##0`	`5`	`-5`	`1`
`$#,##0;($#,##0)`	`$5`	`($5)`	`$1`
`$#,##0.00;` `($#,##0.00)`	`$5.00`	`($5.00)`	`$0.50`
`0%`	`500%`	`-500%`	`50%`
`0.00%`	`500.00%`	`-500.00%`	`50.00%`
`0.00E+00`	`5.00E+00`	`-5.00E+00`	`5.00E-01`
`0.00E-00`	`5.00E00`	`-5.00E00`	`5.00E-01`

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Different Formats for Different Numeric Values (Format Function) | Format Function |
Predefined Numeric Formats (Format Function) | User-Defined Date/Time Formats (Format Function)

FormatCurrency Function

Returns an expression formatted as a currency value using the currency symbol defined in the system control panel.

```
Function FormatCurrency(
   ByVal Expression As Object,
   Optional ByVal NumDigitsAfterDecimal As Integer = -1,
   Optional ByVal IncludeLeadingDigit As TriState = TriState.UseDefault,
   Optional ByVal UseParensForNegativeNumbers As TriState = TriState.UseDefault,
   Optional ByVal GroupDigits As TriState = TriState.UseDefault
) As String
```

Parameters

Expression
Required. Expression to be formatted.

NumDigitsAfterDecimal
Optional. Numeric value indicating how many places are displayed to the right of the decimal. Default value is –1, which indicates that the computer's regional settings are used.

IncludeLeadingDigit
Optional. Tristate enumeration that indicates whether or not a leading zero is displayed for fractional values. See Settings for values.

UseParensForNegativeNumbers
Optional. Tristate enumeration that indicates whether or not to place negative values within parentheses. See Settings for values.

GroupDigits
Optional. Tristate enumeration that indicates whether or not numbers are grouped using the group delimiter specified in the computer's regional settings. See Settings for values.

Settings

The *IncludeLeadingDigit*, *UseParensForNegativeNumbers*, and *GroupDigits* arguments take the following Tristate enumeration values:

Value	Description
TriState.True	True
TriState.False	False
TriState.UseDefault	The computer's regional settings

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	Number of digits after decimal point is greater than 99.
InvalidCastException	13	Type is not numeric.

Remarks

When one or more optional arguments are omitted, the computer's matching regional-settings values are used instead.

The position of the currency symbol relative to the currency value is determined by the system's regional settings.

> **Note** All settings information comes from the locale of the application. By default, that will be the locale set in the control panel. However, it may be changed programmatically by using the .NET Framework, except leading zero, which comes from the **Number** tab.

Example

The following example illustrates the use of the **FormatCurrency** function.

```
Dim myDebt As Double = -4456.43
Dim myString As String
' Returns"($4,456.43)".
MyString = FormatCurrency(myDebt,,, TriState.True, TriState.True)
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

FormatDateTime Function | FormatNumber Function | FormatPercent Function | Tristate Enumeration | ArgumentException | InvalidCastException

FormatDateTime Function

Returns a string expression representing a date/time value.

```
Function FormatDateTime(
   ByVal Expression As DateTime,
   Optional ByVal NamedFormat As DateFormat = DateFormat.GeneralDate
) As String
```

Parameters

Expression
Required. **Date** expression to be formatted.
NamedFormat
Optional. Numeric value that indicates the date/time format used. If omitted, **DateFormat.GeneralDate** is used.

Settings

The *NamedFormat* argument has the following settings:

Constant	Description
DateFormat.GeneralDate	Display a date and/or time. If there is a date part, display it as a short date. If there is a time part, display it as a long time. If present, both parts are displayed.
DateFormat.LongDate	Display a date using the long date format specified in your computer's regional settings.
DateFormat.ShortDate	Display a date using the short date format specified in your computer's regional settings.
DateFormat.LongTime	Display a time using the time format specified in your computer's regional settings.
DateFormat.ShortTime	Display a time using the 24-hour format (hh:mm).

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*NamedFormat* setting is invalid.

Remarks

The **Date** data type always contains both date and time information. For purposes of type conversion, Visual Basic .NET considers 1/1/1 (January 1 of the year 1) to be a neutral value for the date, and 00:00:00 (midnight) to be a neutral value for the time. If you format a **Date** value as a date/time string, **FormatDateTime** does not include neutral values in the resulting string. For example, if you convert #1/1/0001 9:30:00# to a string, the result is "9:30:00 AM"; the date information is suppressed. However, the date information is still present in the original **Date** value and can be recovered with functions such as **DatePart**.

> **Note** If you pass the *Expression* argument as a **String** literal, **FormatDateTime** interprets it according to the **CultureInfo.CurrentCulture** setting of your application. However, if you pass it as a **Date** literal, you should always use the format #mm/dd/yyyy#, because **FormatDateTime** always interprets a **Date** literal according to the English (US) culture. This is necessary because, if an application is developed and coded using **Date** literals from one culture, but is then executed on a platform with a different culture, the **Date** literals could be parsed incorrectly.

Example

This example demonstrates the use of the **FormatDateTime** function.

```
Dim myDate As DateTime = #3/12/1999#   ' English (US) format.
Dim myString As String
' FormatDateTime returns "Friday, March 12, 1999".
' The time information is neutral (00:00:00) and therefore suppressed.
myString = FormatDateTime(myDate, DateFormat.LongDate)
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

FormatCurrency Function | FormatNumber Function | FormatPercent Function | ArgumentException | DatePart Function | CultureInfo Class | CultureInfo.CurrentCulture Property

FormatNumber Function

Returns an expression formatted as a number.

```
Function FormatNumber(
   ByVal Expression As Object,
   Optional ByVal NumDigitsAfterDecimal As Integer = -1,
   Optional ByVal IncludeLeadingDigit As TriState = TriState.UseDefault,
   Optional ByVal UseParensForNegativeNumbers As TriState = TriState.UseDefault,
   Optional ByVal GroupDigits As TriState = TriState.UseDefault
) As String
```

Parameters

Expression
Required. Expression to be formatted.

NumDigitsAfterDecimal
Optional. Numeric value indicating how many places are displayed to the right of the decimal. The default value is –1, which indicates that the computer's regional settings are used.

IncludeLeadingDigit
Optional. Tristate constant that indicates whether a leading zero is displayed for fractional values. See Settings for values.

UseParensForNegativeNumbers
Optional. Tristate constant that indicates whether to place negative values within parentheses. See Settings for values.

GroupDigits
Optional. Tristate constant that indicates whether or not numbers are grouped using the group delimiter specified in the locale settings. See Settings for values.

Settings

The *IncludeLeadingDigit*, *UseParensForNegativeNumbers*, and *GroupDigits* arguments have the following settings:

Constant	Description
TriState.True	True
TriState.False	False
TriState.UseDefault	The computer's regional settings

Exceptions/Errors

Exception type	Error number	Condition
InvalidCastException	13	Type is not numeric.

Remarks

When one or more optional arguments are omitted, the values for omitted arguments are provided by the locale settings.

> **Note** All settings information comes from the locale of the application. By default, that will be the locale set in the control panel. However, it may be changed programmatically by using the .NET Framework.

Example

This example demonstrates the **FormatNumber** function.

```
Dim myNumber As Integer = 45600
Dim myString As String
' Returns "45,600.00".
myString = FormatNumber(myNumber, 2, , ,TriState.True)
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

FormatCurrency Function | FormatDateTime Function | FormatPercent Function | Tristate Enumeration | InvalidCastException

FormatPercent Function

Returns an expression formatted as a percentage (that is, multiplied by 100) with a trailing % character.

```
Function FormatPercent(
   ByVal Expression As Object,
   Optional ByVal NumDigitsAfterDecimal As Integer = -1,
   Optional ByVal IncludeLeadingDigit As TriState = TriState.UseDefault,
   Optional ByVal UseParensForNegativeNumbers As TriState = TriState.UseDefault,
   Optional ByVal GroupDigits As TriState = TriState.UseDefault
) As String
```

Parameters

Expression
Required. Expression to be formatted.

NumDigitsAfterDecimal
Optional. Numeric value indicating how many places to the right of the decimal are displayed. Default value is –1, which indicates that the locale settings are used.

IncludeLeadingDigit
Optional. Tristate constant that indicates whether or not a leading zero is displayed for fractional values. See Settings for values.

UseParensForNegativeNumbers
Optional. Tristate constant that indicates whether or not to place negative values within parentheses. See Settings for values.

GroupDigits
Optional. Tristate constant that indicates whether or not numbers are grouped using the group delimiter specified in the locale settings. See Settings for values.

Settings

The *IncludeLeadingDigit*, *UseParensForNegativeNumbers*, and *GroupDigits* arguments have the following settings:

Constant	Description
TriState.True	True
TriState.False	False
TriState.Default	The computer's regional settings

Exceptions/Errors

Exception type	Error number	Condition
InvalidCastException	13	Type is not numeric.

Remarks

When one or more optional arguments are omitted, the values for omitted arguments are provided by the locale settings.

> **Note** All settings information comes from the locale of the application. By default, that will be the locale set in the control panel. However, it may be changed programmatically by using the .NET Framework.

Example

This example illustrates the use of the **FormatPercent** function:

```
Dim myNumber As Single = 0.76
Dim myString As String
' Returns "76.00%".
myString = FormatPercent(myNumber)
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

FormatCurrency Function | FormatDateTime Function | FormatNumber Function | Tristate Enumeration | InvalidCastException

FreeFile Function

Returns an **Integer** value representing the next file number available for use by the **FileOpen** function.

```
Public Function FreeFile() As Integer
```

Exceptions/Errors

Exception type	Error number	Condition
IOException	67	More than 255 files are in use.

Remarks

Use **FreeFile** to supply a file number that is not already in use.

Example

This example uses the **FreeFile** function to return the next available file number. Five files are opened for output within the loop, and some sample data is written to each.

```
Dim count As Integer
Dim fileNumber As Integer
For count = 1 To 5
   fileNumber = FreeFile()
   FileOpen(fileNumber, "TEST" & count & ".TXT", OpenMode.Output)
   PrintLine(fileNumber, "This is a sample.")
   FileClose(fileNumber)
Next
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

FileOpen Function | IOException Class

FV Function

Returns a **Double** specifying the future value of an annuity based on periodic, fixed payments and a fixed interest rate.

```
Function FV( _
   ByVal Rate As Double, _
   ByVal NPer As Double, _
   ByVal Pmt As Double, _
   Optional ByVal PV As Double = 0, _
   Optional ByVal Due As DueDate = DueDate.EndOfPeriod _
) As Double
```

Parameters

Rate
Required. **Double** specifying interest rate per period. For example, if you get a car loan at an annual percentage rate (APR) of 10 percent and make monthly payments, the rate per period is 0.1/12, or 0.0083.

NPer
Required. **Double** specifying total number of payment periods in the annuity. For example, if you make monthly payments on a four-year car loan, your loan has a total of 4 * 12 (or 48) payment periods.

Pmt
Required. **Double** specifying payment to be made each period. Payments usually contain principal and interest that doesn't change over the life of the annuity.

PV
Optional. **Double** specifying present value (or lump sum) of a series of future payments. For example, when you borrow money to buy a car, the loan amount is the present value to the lender of the monthly car payments you will make. If omitted, 0 is assumed.

Due
Optional. Object of type `Microsoft.VisualBasic.DueDate` that specifies when payments are due. This argument must be either `DueDate.EndOfPeriod` if payments are due at the end of the payment period, or `DueDate.BegOfPeriod` if payments are due at the beginning of the period. If omitted, `DueDate.EndOfPeriod` is assumed.

Remarks

An annuity is a series of fixed cash payments made over a period of time. An annuity can be a loan (such as a home mortgage) or an investment (such as a monthly savings plan).

The *Rate* and *NPer* arguments must be calculated using payment periods expressed in the same units. For example, if *Rate* is calculated using months, *NPer* must also be calculated using months.

For all arguments, cash paid out (such as deposits to savings) is represented by negative numbers; cash received (such as dividend checks) is represented by positive numbers.

Example

This example uses the **FV** function to return the future value of an investment given the percentage rate that accrues per period (`APR / 12`), the total number of payments (`TotPmts`), the payment (`Payment`), the current value of the investment (`PVal`), and a number that indicates whether the payment is made at the beginning or end of the payment period (`PayType`). Note that because `Payment` represents cash paid out, it is a negative number.

```
Sub TestFV()
   Dim Fmt As String
   Dim TotPmts As Integer
   Dim Payment, APR, PVal, Fval As Double
   Dim PayType As DueDate
   Dim Response As MsgBoxResult
   Fmt = "###,###,##0.00"   ' Define money format.
   Payment = CDbl(InputBox("How much do you plan to save each month?"))
   APR = CDbl(InputBox("Enter the expected interest annual percentage rate."))
   If APR > 1 Then APR = APR / 100 ' Ensure proper form.
   TotPmts = CInt(InputBox("For how many months do you expect to save?"))
   Response = MsgBox("Do you make payments at the end of month?", MsgBoxStyle.YesNo)
```

```
    If Response = MsgBoxResult.No Then
       PayType = DueDate.BegOfPeriod
    Else
       PayType = DueDate.EndOfPeriod
    End If
    PVal = CDbl(InputBox("How much is in this savings account now?"))
    Fval = FV(APR / 12, TotPmts, -Payment, -PVal, PayType)
    MsgBox("Your savings will be worth " & Format(Fval, Fmt) & ".")
End Sub
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Financial

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

GetAllSettings Function

Returns a list of key settings and their respective values (originally created with **SaveSetting**) from an application's entry in the Windows registry.

```
Public Function GetAllSettings( _
   ByVal AppName As String, _
   ByVal Section As String _
) As String(,)
```

Parameters

AppName
Required. **String** expression containing the name of the application or project whose key settings are requested.

Section
Required. **String** expression containing the name of the section whose key settings are requested. **GetAllSettings** returns an object that contains a two-dimensional array of strings. The strings contain all the key settings in the specified section plus their corresponding values.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	User is not logged in .

Remarks

GetAllSettings returns an uninitialized **Object** if either *AppName* or *Section* does not exist.

GetAllSettings requires that a user be logged on since it operates under the HKEY_LOCAL_USER registry key, which is not active until a user logs on interactively.

Registry settings that are to be accessed from a non-interactive process (such as mtx.exe) should be stored under either the HKEY_LOCAL_MACHINE\Software\ or the HKEY_USER\DEFAULT\Software registry keys.

Example

This example first uses the **SaveSetting** function to make entries in the Windows registry for the application specified as *AppName*, then uses the **GetAllSettings** function to display the settings. Note that application names and *Section* names can't be retrieved with **GetAllSettings**. Finally, the **DeleteSetting** function removes the application's entries.

```
' Object to hold 2-dimensional array returned by GetAllSettings.
' Integer to hold counter.
Dim MySettings(,) As String
Dim intSettings As Integer
' Place some settings in the registry.
SaveSetting("MyApp", "Startup", "Top", "75")
SaveSetting("MyApp", "Startup", "Left", "50")
' Retrieve the settings.
MySettings = GetAllSettings("MyApp", "Startup")
For intSettings = LBound(MySettings, 1) To UBound(MySettings, 1)
   Debug.WriteLine(MySettings(intSettings, 0))
   Debug.WriteLine(MySettings(intSettings, 1))
Next intSettings
DeleteSetting("MyApp")
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: Interaction

Assembly: Microsoft.Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

DeleteSetting Function | GetSetting Function | SaveSetting Function | ArgumentException Class

GetAttr Function

Returns a **FileAttribute** value representing the attributes of a file, directory, or folder.

```
Public Function GetAttr(ByVal PathName As String) As FileAttribute
```

Parameter

PathName
Required. **String** expression that specifies a file, directory, or folder name. *PathName* may include the directory or folder, and the drive.

Return Values

The value returned by **GetAttr** is the sum of the following enumeration values:

Value	Constant	Description
Normal	**vbNormal**	Normal.
ReadOnly	**vbReadOnly**	Read-only.
Hidden	**vbHidden**	Hidden.
System	**vbSystem**	System file.
Directory	**vbDirectory**	Directory or folder.
Archive	**vbArchive**	File has changed since last backup.
Alias	**vbAlias**	File has a different name.

Note These enumerations are specified by the Visual Basic language. The names can be used anywhere in your code in place of the actual values.

Exceptions/Errors

Exception type	Error number	Condition
IOException	52	*Pathname* is invalid or contains wildcards .
FileNotFoundException	53	Target file does not exist.

Remarks

To determine which attributes are set, use the **And** operator to perform a bitwise comparison of the value returned by the **GetAttr** function and the value of the individual file attribute you want. If the result is not zero, that attribute is set for the named file. For example, the return value of the following **And** expression is zero if the Archive attribute is not set:

```
Result = GetAttr(FName) And vbArchive
```

A nonzero value is returned if the **Archive** attribute is set.

Example

This example uses the **GetAttr** function to determine the attributes of a file and directory or folder.

```
Dim MyAttr As FileAttribute
' Assume file TESTFILE is normal and readonly.
MyAttr = GetAttr("C:\TESTFILE.txt")   ' Returns vbNormal.

' Test for normal.
If (MyAttr And FileAttribute.Normal) = FileAttribute.Normal Then
   MsgBox("This file is normal.")
End If

' Test for normal and readonly.
```

```
Dim normalReadonly As FileAttribute
normalReadonly = FileAttribute.Normal Or FileAttribute.ReadOnly
If (MyAttr And normalReadonly) = normalReadonly Then
   MsgBox("This file is normal and readonly.")
End If

' Assume MYDIR is a directory or folder.
MyAttr = GetAttr("C:\MYDIR")
If (MyAttr And FileAttribute.Directory) = FileAttribute.Directory Then
   MsgBox("MYDIR is a directory")
End If
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in MicrosoftVisualBasic.dll)

See Also

And Operator | FileAttr Function | SetAttr Function | IOException Class | FileNotFoundException Class | FileAttribute Enumeration

GetChar Function

Returns a **Char** value representing the character from the specified index in the supplied string.

```
Public Shared Function GetChar( _
   ByVal Str As String, _
   ByVal Index As Integer _
) As Char
```

Parameters

Str
Required. Any valid **String** expression.
Index
Required. **Integer** expression. The (1-based) index of the character in *Str* to be returned.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Str* is **Nothing**, *Index* < 1, or *Index* is greater than index of last character of *Str*.

Remarks

If *Index* is less than 1 or greater than the index of the last character in *Str*, an **ArgumentException** is thrown.

Example

This example shows how to use the **GetChar** function to return a character from a specified index in a **String**.

```
Dim myString As String = "ABCDE"
Dim myChar As Char
myChar = GetChar(myString, 4)   ' myChar = "D"
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Mid Function | ArgumentException Class

GetException Function

Returns the exception representing the error that occurred.

```
Overridable Public Function GetException() As Exception
```

Remarks

The **GetException** function is available only from the **Err** object class. It works with the **Exception** property of the **Err** object to display the error that has occurred.

Example

The following code displays the message assigned to the exception in the **Err** object:

```
On Error Resume Next
Dim myError As System.Exception
' Generate an overflow exception.
Err.Raise(6)
' Assigns the exception from the Err object to myError.
myError = Err.GetException()
' Displays the message associated with the exception.
MsgBox(myError.Message)
```

Requirements

Namespace: Microsoft.VisualBasic

Class: Err Object

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Err Object | Structured Exception Handling | Unstructured Exception Handling

GetObject Function

Returns a reference to an object provided by a COM component.

```
Public Function GetObject( _
   Optional ByVal PathName As String = Nothing, _
   Optional ByVal Class As String = Nothing _
) As Object
```

Parameters

PathName
Optional; **String**. The full path and name of the file containing the object to retrieve. If *pathname* is omitted, *class* is required.
Class
Optional; **String**. A string representing the class of the object.

The *Class* argument has the following syntax and parts:

```
appname.objecttype
```

Class Parameters

appname
Required; **String**. The name of the application providing the object.
objecttype
Required; **String**. The type or class of object to create.

Exceptions/Errors

Exception type	Error number	Condition
Exception	429	No object with the specified pathname exists.
FileNotFoundException	432	No object of the specified type exists.

Remarks

Use the **GetObject** function to load an instance of a COM component from a file. For example:

```
Dim CADObject As Object
CADObject = GetObject("C:\CAD\SCHEMA.CAD")
```

When this code is executed, the application associated with the specified *pathname* is started and the object in the specified file is activated.

If *PathName* is a zero-length string (""), **GetObject** returns a new object instance of the specified type. If the *PathName* argument is omitted, **GetObject** returns a currently active object of the specified type. If no object of the specified type exists, an error occurs.

Some applications allow you to activate a sub-object associated with a file. Add an exclamation point (**!**) to the end of the file name and follow it with a string that identifies the part of the file you want to activate. For information on how to create this string, see the documentation for the application that created the object.

For example, in a drawing application you might have multiple layers to a drawing stored in a file. You could use the following code to activate a layer within a drawing called `SCHEMA.CAD`:

```
LayerObject = GetObject("C:\CAD\SCHEMA.CAD!Layer3")
```

If you don't specify the object's *Class*, Automation determines the application to start and the object to activate, based on the file name you provide. Some files, however, may support more than one class of object. For example, a drawing might support three

different types of objects: an Application object, a Drawing object, and a Toolbar object, all of which are part of the same file. To specify which object in a file you want to activate, use the optional *Class* argument. For example:

```
Dim MyObject As Object
MyObject = GetObject("C:\DRAWINGS\SAMPLE.DRW", "FIGMENT.DRAWING")
```

In the example, `FIGMENT` is the name of a drawing application and `DRAWING` is one of the object types it supports.

Once an object is activated, you reference it in code using the object variable you defined. In the preceding example, you access properties and methods of the new object using the object variable `MyObject`. For example:

```
MyObject.Line (9, 90)
MyObject.InsertText (9, 100, "Hello, world.")
MyObject.SaveAs ("C:\DRAWINGS\SAMPLE.DRW")
```

> **Note** Use the **GetObject** function when there is a current instance of the object or if you want to create the object with a file already loaded. If there is no current instance, and you do not want the object started with a file loaded, use the **CreateObject** function. If an object has registered itself as an Active-X single-instance object, only one instance of the object is created, no matter how many times **CreateObject** is executed. With a single-instance object, **GetObject** always returns the same instance when called with the zero-length string ("") syntax, and it causes an error if the *PathName* argument is omitted. You cannot use **GetObject** to obtain a reference to a class created with Visual Basic.

Example

This example uses the **GetObject** function to get a reference to a specific Microsoft Excel worksheet (`MyXL`). It uses the worksheet's Application property to make Microsoft Excel visible, to close it, and so on. Using two API calls, the `DetectExcel` sub procedure looks for Microsoft Excel, and if it is running, enters it in the running object table. The first call to **GetObject** causes an error if Microsoft Excel isn't already running. In the example, the error causes the `ExcelWasNotRunning` flag to be set to `True`. The second call to **GetObject** specifies a file to open. If Microsoft Excel isn't already running, the second call starts it and returns a reference to the worksheet represented by the specified file, `test.xls`. The file must exist in the specified location; otherwise, the Visual Basic error Automation error is generated. Next the example code makes both Microsoft Excel and the window containing the specified worksheet visible.

Option Strict Off is required because this example uses late binding, where objects are assigned to generic object variables. You can specify **Option Strict On** and declare objects of specific object types if you add a reference to the Excel type library from the **COM** tab of the **Add Reference** dialog box of the **Project** menu in Visual Studio .NET.

```
' Add Option Strict Off to the top of your program.
Option Strict Off
 ' Declare necessary API routines:
   Declare Function FindWindow Lib "user32" Alias _
      "FindWindowA" (ByVal lpClassName As String, _
      ByVal lpWindowName As Long) As Long

   Declare Function SendMessage Lib "user32" Alias _
   "SendMessageA" (ByVal hWnd As Long, ByVal wMsg As Long, _
      ByVal wParam As Long, ByVal lParam As Long) As Long

Sub GetExcel()
   Dim MyXL As Object   ' Variable to hold reference
   ' to Microsoft Excel.
   Dim ExcelWasNotRunning As Boolean   ' Flag for final release.

   ' Test to see if there is a copy of Microsoft Excel already running.
   On Error Resume Next   ' Defer error trapping.
   ' Getobject function called without the first argument returns a
   ' reference to an instance of the application.
   ' If the application is not running, an error occurs.
   MyXL = GetObject(, "Excel.Application")
   If Err().Number <> 0 Then ExcelWasNotRunning = True
   Err().Clear() ' Clear Err object in case error occurred.

   ' Check for Microsoft Excel. If Microsoft Excel is running,
   ' enter it into the Running Object table.
```

```
    DetectExcel()

    ' Set the object variable to reference the file you want to see.
    MyXL = GetObject("c:\vb\TEST.XLS")

    ' Show Microsoft Excel through its Application property. Then
    ' show the actual window containing the file using the Windows
    ' collection of the MyXL object reference.
    MyXL.Application.Visible = True
    MyXL.Parent.Windows(1).Visible = True
    '  Do manipulations of your  file here.
    '
End Sub

Sub DetectExcel()
    ' Procedure dectects a running Excel and registers it.
    Const WM_USER = 1024
    Dim hWnd As Long
    ' If Excel is running this API call returns its handle.
    hWnd = FindWindow("XLMAIN", 0)
    If hWnd = 0 Then   ' 0 means Excel not running.
       Exit Sub
    Else
       ' Excel is running so use the SendMessage API
       ' function to enter it in the Running Object Table.
       SendMessage(hWnd, WM_USER + 18, 0, 0)
    End If
End Sub
```

When you call the `GetExcel` function, a check is made to see if Excel is already running. If it is not, then an instance of Excel is created.

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: Interaction

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

CreateObject Function | Declare Statement | Exception Class | FileNotFoundException Class

GetSetting Function

Returns a key setting value from an application's entry in the Windows registry.

```
Public Function GetSetting( _
   ByVal AppName As String, _
   ByVal Section As String, _
   ByVal Key As String, _
   Optional ByVal Default As String = "" _
) As String
```

Parameters

AppName
Required. **String** expression containing the name of the application or project whose key setting is requested.
Section
Required. **String** expression containing the name of the section in which the key setting is found.
Key
Required. **String** expression containing the name of the key setting to return.
Default
Optional. Expression containing the value to return if no value is set in the *Key* setting. If omitted, *Default* is assumed to be a zero-length string ("").

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	One or more arguments are not **String** expressions, or user is not logged in.

Remarks

If any of the items named in the **GetSetting** arguments do not exist, **GetSetting** returns a value of *Default*.

GetSetting requires that a user be logged on since it operates under the HKEY_LOCAL_USER registry key, which is not active until a user logs on interactively.

Registry settings that are to be accessed from a non-interactive process (such as mtx.exe) should be stored under either the HKEY_LOCAL_MACHINE\Software\ or the HKEY_USER\DEFAULT\Software registry keys.

GetSetting requires **Read** Registry Permission.

Example

This example first uses the **SaveSetting** function to make entries in the Windows registry for the application specified as *AppName*, and then uses the **GetSetting** function to display one of the settings. Because the *Default* argument is specified, some value is guaranteed to be returned. Note that *Section* names can't be retrieved with **GetSetting**. Finally, the **DeleteSetting** function removes all the application's entries.

```
' Place some settings in the registry.
SaveSetting("MyApp", "Startup", "Top", "75")
SaveSetting("MyApp", "Startup", "Left", "50")
Console.WriteLine(GetSetting("MyApp", "Startup", "Left", "25"))
DeleteSetting("MyApp")
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: Interaction

Assembly: Microsoft.Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

H-L Functions

The following table contains a listing of the Visual Basic .NET run-time member functions.

Hex	Hour	IIf	Input
InputBox	InputString	InStr	InStrRev
Int	IPmt	IRR	IsArray
IsDate	IsDBNull	IsError	IsNothing
IsNumeric	IsReference	Join	Kill
LBound	LCase	Left	Len
LineInput	Loc	Lock	LOF
Log	LSet	LTrim	

See Also

A-C Functions | D-G Functions | M-R Functions | S-Z Functions | Visual Basic Language and Run-Time Reference

Hex Function

Returns a string representing the hexadecimal value of a number.

```
Public Shared Function Hex( _
   ByVal Number As { Byte | Short | Integer | Long | Object } _
) As String
```

Parameter

Number
Required. Any valid numeric expression or **String** expression.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentNullException	5	*Number* is not specified.
ArgumentException	5	*Number* is not a numeric type .

Remarks

If *Number* is not already a whole number, it is rounded to the nearest whole number before being evaluated.

If *Number* is	Hex returns
Empty	Zero (0)
Any numeric value	Up to sixteen hexadecimal characters

You can represent hexadecimal numbers directly by preceding numbers in the proper range with **&H**. For example, `&H10` represents decimal 16 in hexadecimal notation.

Example

This example uses the **Hex** function to return the hexadecimal value of a number.

```
Dim MyHex As String
MyHex = Hex(5)   ' Returns 5.
MyHex = Hex(10)   ' Returns A.
MyHex = Hex(459)   ' Returns 1CB.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Conversion

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Oct Function | Type Conversion Functions | ArgumentNullException Class

Hour Function

Returns an **Integer** value from 0 through 23 representing the hour of the day.

```
Public Function Hour(ByVal TimeValue As DateTime) As Integer
```

Parameter

TimeValue
Required. **Date** value from which you want to extract the hour.

You can also obtain the hour of the day by calling **DatePart** and specifying **DateInterval.Hour** for the *Interval* argument.

Example

This example uses the **Hour** function to obtain the hour from a specified time. In the development environment, the time literal is displayed in short time format using the locale settings of your code.

```
Dim MyTime As Date
Dim MyHour As Integer
MyTime = #4:35:17 PM#   ' Assign a time.
MyHour = Hour(MyTime)   ' MyHour contains 16.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: DateAndTime

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Day Function | Minute Function | Now Property | Second Function | TimeOfDay Property | DatePart Function | System Namespace | DateTime Structure | ArgumentException Class | ArgumentOutOfRangeException Class

IIf Function

Returns one of two objects, depending on the evaluation of an expression.

```
Public Function IIf( _
   ByVal Expression As Boolean, _
   ByVal TruePart As Object, _
   ByVal FalsePart As Object _
) As Object
```

Parameters

Expression
Required. **Boolean**. The expression you want to evaluate.
TruePart
Required. **Object**. Returned if *Expression* evaluates to **True**.
FalsePart
Required. **Object**. Returned if *Expression* evaluates to **False**.

Remarks

> **Note** The expressions in the argument list can include function calls. As part of preparing the argument list for the call to **IIf**, the Visual Basic compiler calls every function in every expression. This means that you cannot rely on a particular function not being called if the other argument is selected by *Expression*.

Example

This example uses the **IIf** function to evaluate the `TestMe` parameter of the `CheckIt` procedure and returns the word "Large" if the amount is greater than 1000; otherwise, it returns the word "Small".

```
Function CheckIt (ByVal TestMe As Integer) As String
   CheckIt = IIf(TestMe > 1000, "Large", "Small")
End Function
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Interaction

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Choose Function | If...Then...Else Statements | Select...Case Statements | Switch Function

Input Function

Reads data from an open sequential file and assigns the data to variables.

```
Public Sub Input( _
   FileNumber As Integer, _
   ByRef Value As Object _
)
```

Parameters

FileNumber
Required. Any valid file number.
Value
Required. Variable that is assigned the values read from the file — can't be an array or object variable.

Exceptions/Errors

Exception type	Error number	Condition
IOException	52	*FileNumber* does not exist.
IOException	54	File mode is invalid.

Remarks

Data read with **Input** is usually written to a file with **Write**. Use this function only with files opened in **Input** or **Binary** mode.

> **Security Note** When reading from files, do not make decisions about the contents of the file based on the file name extension. For example, a file named Form1.vb may not be a Visual Basic .NET source file.

When read, standard string or numeric data is assigned to variables without modification. The following table illustrates how other input data are treated:

Data	Value assigned to variable
Delimiting comma or blank line	Empty
#NULL#	**DBNull**
#TRUE# or #FALSE#	**True** or **False**
#yyyy-mm-dd hh:mm:ss#	The date and/or time represented by the expression
#ERROR *errornumber#*	*errornumber* (variable is an object tagged as an error)

If you reach the end of the file while you are inputting a data item, the input is terminated and an error occurs.

Note The **Input** function is not localized. For example, in the German version, if you input 3,14159, it will return only 3, since the comma is treated as a variable separator, rather than a decimal point.

> **Security Note** Reading from a file with the **Input** function requires **Read** access from the **FileIOPermissionAccess** enumeration. For more information, see FileIOPermissionAccess Enumeration.

Example

This example uses the **Input** function to read data from a file into two variables. This example assumes that `TESTFILE` is a file with a few lines of data written to it using the **Write** function; that is, each line contains a string in quotations and a number separated by a comma, for example, ("Hello", 234).

```
FileOpen(1, "TESTFILE", OpenMode.Output)
Write(1, "hello")
Write(1, 14)
FileClose(1)

Dim s As String
Dim i As Integer
FileOpen(1, "TESTFILE", OpenMode.Input)
```

```
Input(1, s)
Debug.WriteLine(s)
Input(1, i)
Debug.WriteLine(i)
FileClose(1)
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

InputString Function | FileOpen Function | Print, PrintLine Functions | Write, WriteLine Functions | File Access with Visual Basic Run-Time Functions| IOException Class

InputBox Function

Displays a prompt in a dialog box, waits for the user to input text or click a button, and then returns a string containing the contents of the text box.

```
Public Function InputBox( _
   ByVal Prompt As String, _
   Optional ByVal Title As String = "", _
   Optional ByVal DefaultResponse As String = "", _
   Optional ByVal XPos As Integer = -1, _
   Optional ByVal YPos As Integer = -1 _
) As String
```

Parameters

Prompt
Required. **String** expression displayed as the message in the dialog box. The maximum length of *Prompt* is approximately 1024 characters, depending on the width of the characters used. If *Prompt* consists of more than one line, you can separate the lines using a carriage return character (**Chr(**13**)**), a linefeed character (**Chr(**10**)**), or a carriage return–linefeed character combination (**Chr(**13**)** & **Chr(**10**)**) between each line.

Title
Optional. **String** expression displayed in the title bar of the dialog box. If you omit *Title*, the application name is placed in the title bar.

DefaultResponse
Optional. **String** expression displayed in the text box as the default response if no other input is provided. If you omit *DefaultResponse*, the displayed text box is empty.

XPos
Optional. Numeric expression that specifies, in twips, the distance of the left edge of the dialog box from the left edge of the screen. If you omit *XPos*, the dialog box is centered horizontally.

YPos
Optional. Numeric expression that specifies, in twips, the distance of the upper edge of the dialog box from the top of the screen. If you omit *YPos*, the dialog box is positioned vertically approximately one-third of the way down the screen.

Remarks

To specify more than the first argument, you must use the **InputBox** function in an expression. If you omit any positional arguments, you must retain the corresponding comma delimiter.

> **Note** The **InputBox** function requires UIPermission at the SafeTopLevelWindows level, which may affect its execution in partial trust situations. For more information, see Requesting Permissions and UIPermission Class.

Example

This example shows various ways to use the **InputBox** function to prompt the user to enter a value. If the x and y positions are omitted, the dialog box is automatically centered for the respective axes. The variable `MyValue` contains the value entered by the user if the user clicks OK or presses the ENTER key. If the user clicks Cancel, a zero-length string is returned.

```
Dim message, title, defaultValue As String
Dim myValue As Object
message = "Enter a value between 1 and 3"   ' Set prompt.
title = "InputBox Demo"   ' Set title.
DefaultValue = "1"   ' Set default value.

' Display message, title, and default value.
myValue = InputBox(message, title, defaultValue)

' Display dialog box at position 100, 100.
myValue = InputBox(message, title, defaultValue, 100, 100)
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Interaction

Assembly: Microsoft.Visual Basic .NET Runtime (in MicrosoftVisualBasic.dll)

See Also

MsgBox Function | Chr, ChrW Functions

InputString Function

Returns **String** value containing characters from a file opened in **Input** or **Binary** mode.

```
InputString(_
   ByVal FileNumber As Integer, _
   ByVal CharCount As Integer _
) As String
```

Parameters

FileNumber
Required. Any valid file number.
CharCount
Required. Any valid numeric expression specifying the number of characters to read.

Exceptions/Errors

Exception type	Error number	Condition
IOException	52	*FileNumber* does not exist.
ArgumentException	5	*CharCount* < 0 or > 2^{14}.

Remarks

Data read with the **InputString** function is usually written to a file with **Print** or **FilePut**. Use this function only with files opened in **Input** or **Binary** mode.

Unlike the **Input** function, the **InputString** function returns all of the characters it reads, including commas, carriage returns, linefeeds, quotation marks, and leading spaces.

With files opened for **Binary** access, an attempt to read through the file using the **InputString** function until **EOF** returns **True** generates an error. Use the **LOF** and **Loc** functions instead of **EOF** when reading binary files with **InputString**, or use File**Get** when using the **EOF** function.

> **Security Note** When reading from files, do not make decisions about the contents of the file based on the file name extension. For example, a file named Form1.vb may not be a Visual Basic .NET source file.

Example

This example uses the **InputString** function to read one character at a time from a file and print it to the **Output** window. This example assumes that `MYFILE` is a text file with a few lines of sample data.

```
Dim oneChar As Char
FileOpen(1,  "MYFILE.TXT", OpenMode.Input) ' Open file.
While Not EOF(1)   ' Loop until end of file.
oneChar = (InputString(1, 1))   ' Get one character.
System.Console.Out.WriteLine(oneChar)   ' Print to the output window.
End While
FileClose(1)
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Input Function | IOException Class | ArgumentExceptionClass

InStr Function

Returns an integer specifying the start position of the first occurrence of one string within another.

```
Public Shared Function InStr(_
   Optional ByVal Start As Integer, _
   ByVal String1 As String, _
   ByVal String2 As String, _
) As Integer
```

-or-

```
Public Shared Function InStr(_
   Optional ByVal Start As Integer, _
   ByVal String1 As String, _
   ByVal String2 As String, _
   Optional ByVal Compare As Microsoft.VisualBasic.CompareMethod _
) As Integer
```

Parameters

Start
Optional. Numeric expression that sets the starting position for each search. If omitted, search begins at the first character position. The start index is 1 based.

String1
Required. **String** expression being searched.

String2
Required. **String** expression sought.

Compare
Optional. Specifies the type of string comparison. If *Compare* is omitted, the **Option Compare** setting determines the type of comparison. Specify a valid LCID (**LocaleID**) to use locale-specific rules in the comparison.

Settings

The *compare* argument settings are:

Constant	Value	Description
Binary	0	Performs a binary compariso n
Text	1	Performs a text comparison

Return Values

If	InStr returns
String1 is zero length or **Nothing**	0
String2 is zero length or **Nothing**	*start*
String2 is not found	0
String2 is found within *String1*	Position where match begins
Start > *String2*	0

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Start* < 1.

Note The **InStrB** function in previous versions of Visual Basic returns a number of bytes rather than a character position. It is used primarily for converting strings in double-byte character set (DBCS) applications. All Visual Basic .NET strings are in Unicode, and **InStrB** is no longer supported.

Example

This example uses the **InStr** function to return the position of the first occurrence of one string within another.

```
Dim SearchString, SearchChar As String
Dim MyPos As Integer

SearchString ="XXpXXpXXPXXP"   ' String to search in.
SearchChar = "P"   ' Search for "P".

' A textual comparison starting at position 4. Returns 6.
MyPos = InStr(4, SearchString, SearchChar, CompareMethod.Text)

' A binary comparison starting at position 1. Returns 9.
MyPos = InStr(1, SearchString, SearchChar, CompareMethod.Binary)

' Comparison is binary by default (last argument is omitted).
MyPos = InStr(SearchString, SearchChar)   ' Returns 9.

MyPos = InStr(1, SearchString, "W")   ' Returns 0.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Strings | String Manipulation | InStrRev Function | Option Compare Statement | StrComp Function | ArgumentException Class | Programming Element Support Changes Summary

InStrRev Function

Returns the position of the first occurrence of one string within another, starting from the right side of the string.

```
Public Function InStrRev(
   ByVal StringCheck As String,
   ByVal StringMatch As String,
   Optional ByVal Start As Integer = -1,
   Optional ByVal Compare As CompareMethod = CompareMethod.Binary
) As Integer
```

Parameters

StringCheck
Required. String expression being searched.
StringMatch
Required. String expression being searched for.
Start
Optional. Numeric expression that sets the one-based starting position for each search, starting from the left side of the string. If *Start* is omitted, –1 is used, which means that the search begins at the last character position. Search then proceeds from right to left.
Compare
Optional. Numeric value indicating the kind of comparison to use when evaluating substrings. If omitted, a binary comparison is performed. See Settings for values.

Settings

The *Compare* argument can have the following values:

Constant	Description
Binary	Performs a binary comparison
Text	Performs a textual compariso n

Return Values

InStrRev returns the following values:

If	InStrRev returns
StringCheck is zero-length	0
StringMatch is zero-length	*start*
StringMatch is not found	0
StringMatch is found within *StringCheck*	Position at which the first match is found, starting with the left side of th e string.
Start is greater than length of *StringMatch*	0

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Start* = 0 or *Start* < -1 .

Remarks

Note that the syntax for the **InStrRev** function is not the same as the syntax for the **InStr** function.

Example

This example demonstrates the use of the **InStrRev** function:

```
Dim myString As String = "the quick brown fox jumps over the lazy dog"
Dim myNumber As Integer
MyNumber = InStrRev(myString, "the")   ' Returns 32.
MyNumber = InStrRev(myString, "the", 16)   ' Returns 1
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

InStr Function | Strings | String Manipulation

Int, Fix Functions

Return the integer portion of a number.

```
Public Shared Function Int(ByVal number As { Double | Integer | Long | Object | Short | Singl
e | Decimal }) As { Double | Integer | Long | Object | Short | Single | Decimal }
Public Shared Function Fix(ByVal number As { Double | Integer | Long | Object | Short | Singl
e | Decimal }) As { Double | Integer | Long | Object | Short | Single | Decimal }
```

Parameter

number
Required. A number of type **Double** or any valid numeric expression. If *number* contains Nothing, **Nothing** is returned.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentNullException	5	*Number* is not specified.
ArgumentException	5	*Number* is not a numeric type .

Remarks

Both the **Int** and **Fix** functions remove the fractional part of *number* and return the resulting integer value.

The difference between **Int** and **Fix** functions is that if *number* is negative, **Int** returns the first negative integer less than or equal to *number*, whereas **Fix** returns the first negative integer greater than or equal to *number*. For example, **Int** converts -8.4 to -9, and **Fix** converts -8.4 to -8.

`Fix(number)` is equivalent to `Sign(number) * Int(Abs(number))`.

Example

This example illustrates how the **Int** and **Fix** functions return integer portions of numbers. In the case of a negative number argument, the **Int** function returns the first negative integer less than or equal to the number; the **Fix** function returns the first negative integer greater than or equal to the number. The following example requires you to specify **Option Strict Off** because implicit conversions from type **Double** to type **Integer** are not allowed under **Option Strict On**:

```
Option Strict Off
' Code will not function unless placed within a Sub or Function
Dim MyNumber As Integer
MyNumber = Int(99.8)   ' Returns 99.
MyNumber = Fix(99.8)   ' Returns 99.

MyNumber = Int(-99.8)   ' Returns -100.
MyNumber = Fix(-99.8)   ' Returns -99.

MyNumber = Int(-99.2)   ' Returns -100.
MyNumber = Fix(-99.2)   ' Returns -99.
```

You can use the **CInt** function to explicitly convert other data types to type **Integer** with **Option Strict Off**. However, **Cint** rounds to the nearest integer instead of truncating the fractional part of numbers. For example:

```
MyNumber = CInt(99.8)    ' Returns 100.
MyNumber = CInt(-99.8)   ' Returns -100.
MyNumber = CInt(-99.2)   ' Returns -99.
```

You can use the **CInt** function on the result of a call to **Fix** or **Int** to perform explicit conversion to integer without rounding. For example:

```
MyNumber = CInt(Fix(99.8))   ' Returns 99.
MyNumber = CInt(Int(99.8))   ' Returns 99.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Conversion

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

CInt Function | Integer Data Type | Math Summary | Math Functions | ArgumentNullException Class

IPmt Function

Returns a **Double** specifying the interest payment for a given period of an annuity based on periodic, fixed payments and a fixed interest rate.

```
Function IPmt( _
   ByVal Rate As Double, _
   ByVal Per As Double, _
   ByVal NPer As Double, _
   ByVal PV As Double, _
   Optional ByVal FV As Double = 0, _
   Optional ByVal Due As DueDate = DueDate.EndOfPeriod _
) As Double
```

Parameters

Rate
Required. **Double** specifying interest rate per period. For example, if you get a car loan at an annual percentage rate (APR) of 10 percent and make monthly payments, the rate per period is 0.1/12, or 0.0083.

Per
Required. **Double** specifying payment period in the range 1 through *NPer*.

NPer
Required. **Double** specifying total number of payment periods in the annuity. For example, if you make monthly payments on a four-year car loan, your loan has a total of 4 * 12 (or 48) payment periods.

PV
Required. **Double** specifying present value, or value today, of a series of future payments or receipts. For example, when you borrow money to buy a car, the loan amount is the present value to the lender of the monthly car payments you will make.

FV
Optional. **Double** specifying future value or cash balance you want after you've made the final payment. For example, the future value of a loan is $0 because that's its value after the final payment. However, if you want to save $50,000 over 18 years for your child's education, then $50,000 is the future value. If omitted, 0 is assumed.

Due
Optional. Object of type `Microsoft.VisualBasic.DueDate` that specifies when payments are due. This argument must be either `DueDate.EndOfPeriod` if payments are due at the end of the payment period, or `DueDate.BegOfPeriod` if payments are due at the beginning of the period. If omitted, `DueDate.EndOfPeriod` is assumed.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Per* is invalid.

Remarks

An annuity is a series of fixed cash payments made over a period of time. An annuity can be a loan (such as a home mortgage) or an investment (such as a monthly savings plan).

The *Rate* and *NPer* arguments must be calculated using payment periods expressed in the same units. For example, if *Rate* is calculated using months, *NPer* must also be calculated using months.

For all arguments, cash paid out (such as deposits to savings) is represented by negative numbers; cash received (such as dividend checks) is represented by positive numbers.

Example

This example uses the **IPmt** function to calculate how much of a payment is interest when all the payments are of equal value. Given are the interest percentage rate per period (`APR / 12`), the payment period for which the interest portion is desired (`Period`), the total number of payments (`TotPmts`), the present value or principal of the loan (`PVal`), the future value of the loan (`FVal`), and a number that indicates whether the payment is due at the beginning or end of the payment period (`PayType`).

```
Sub TestIPMT()
   Dim Fmt, Msg As String
```

```
    Dim APR, PVal, Fval, Period, IntPmt, TotInt, TotPmts As Double
    Dim PayType As DueDate
    Dim Response As MsgBoxResult

    Fval = 0   ' Usually 0 for a loan.
    Fmt = "###,###,##0.00"   ' Define money format.
    PVal = CDbl(InputBox("How much do you want to borrow?"))
    APR = CDbl(InputBox("What is the annual percentage rate of your loan?"))
    If APR > 1 Then APR = APR / 100 ' Ensure proper form.
    TotPmts = CInt(InputBox("How many monthly payments?"))
    Response = MsgBox("Do you make payments at end of the month?", MsgBoxStyle.YesNo)
    If Response = MsgBoxResult.No Then
       PayType = DueDate.BegOfPeriod
    Else
       PayType = DueDate.EndOfPeriod
    End If
    For Period = 1 To TotPmts   ' Total all interest.
       IntPmt = IPmt(APR / 12, Period, TotPmts, -PVal, Fval, PayType)
       TotInt = TotInt + IntPmt
    Next Period
    Msg = "You'll pay a total of " & Format(TotInt, Fmt)
    Msg = Msg & " in interest for this loan."
    MsgBox(Msg)    ' Display results.
 End Sub
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Financial

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

DDB Function | IRR Function | MIRR Function | NPer Function | NPV Function | Pmt Function | PPmt Function | PV Function | Rate Function | SLN Function | SYD Function | ArgumentException Class

IRR Function

Returns a **Double** specifying the internal rate of return for a series of periodic cash flows (payments and receipts).

```
Function IRR( _
    ByRef ValueArray() As Double, _
   Optional ByVal Guess As Double = 0.1 _
) As Double
```

Parameters

ValueArray()
Required. Array of **Double** specifying cash flow values. The array must contain at least one negative value (a payment) and one positive value (a receipt).

Guess
Optional. Object specifying value you estimate will be returned by **IRR**. If omitted, *Guess* is 0.1 (10 percent).

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	Array argument values are invalid.

Remarks

The internal rate of return is the interest rate received for an investment consisting of payments and receipts that occur at regular intervals.

The **IRR** function uses the order of values within the array to interpret the order of payments and receipts. Be sure to enter your payment and receipt values in the correct sequence. The cash flow for each period doesn't need to be fixed, as it is for an annuity.

IRR is calculated by iteration. Starting with the value of *Guess*, **IRR** cycles through the calculation until the result is accurate to within 0.00001 percent. If **IRR** can't find a result after 20 tries, it fails.

Example

In this example, the **IRR** function returns the internal rate of return for a series of 5 cash flows contained in the array `Values()`. The first array element is a negative cash flow representing business start-up costs. The remaining 4 cash flows represent positive cash flows for the subsequent 4 years. `Guess` is the estimated internal rate of return.

```
Sub TestIRR()
   Dim Guess, RetRate, Values(4) As Double
   Dim Fmt, Msg As String
   Guess = 0.1  ' Guess starts at 10 percent.
   Fmt = "#0.00"   ' Define percentage format.
   Values(0) = -70000   ' Business start-up costs.
   ' Positive cash flows reflecting income for four successive years.
   Values(1) = 22000 : Values(2) = 25000
   Values(3) = 28000 : Values(4) = 31000
   RetRate = IRR(Values, Guess) * 100   ' Calculate internal rate.
   Msg = "The internal rate of return for these five cash flows is "
   Msg = Msg & Format(RetRate, CStr(Fmt)) & " percent."
   MsgBox(Msg)    ' Display internal return rate.
End Sub
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Financial

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

DDB Function | FV Function | IPmt Function | MIRR Function | NPer Function | NPV Function | Pmt Function | PPmt Function | PV Function | Rate Function | SLN Function | SYD Function | ArgumentException Class

IsArray Function

Returns a **Boolean** value indicating whether a variable points to an array.

```
Public Function IsArray(ByVal VarName As Object) As Boolean
```

Parameter

VarName
Required. **Object** variable.

Remarks

IsArray returns **True** if the variable points to an array; otherwise, it returns **False**. **IsArray** is especially useful with objects containing arrays.

Example

This example uses the **IsArray** function to check if several variables refer to an array.

```
Dim MyArray(4), YourArray(3) As Integer   ' Declare array variables.
Dim MyString As String
Dim MyCheck As Boolean
MyCheck = IsArray(MyArray)   ' Returns True.
MyCheck = IsArray(YourArray)   ' Returns True.
MyCheck = IsArray(MyString)   ' Returns False.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Information

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Declaring Array Variables | IsDate Function | IsDBNull Function | IsError Function | IsNothing Function | IsNumeric Function | IsReference Function | Object Data Type | TypeName Function

IsDate Function

Returns a **Boolean** value indicating whether an expression can be converted to a date.

```
Public Function IsDate(ByVal Expression As Object) As Boolean
```

Parameter

Expression
Required. **Object** expression.

Remarks

IsDate returns **True** if the expression is of type **Date** or is a string convertible to type **Date**; otherwise, it returns **False**.

Example

This example uses the **IsDate** function to determine if several variables can be converted to dates.

```
Dim MyDate, YourDate As Date
Dim NoDate As String
Dim MyCheck As Boolean
MyDate = "February 12, 1969"
YourDate = #2/12/1969#
NoDate = "Hello"
MyCheck = IsDate(MyDate)   ' Returns True.
MyCheck = IsDate(YourDate)   ' Returns True.
MyCheck = IsDate(NoDate)   ' Returns False.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Information

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

IsArray Function | IsDBNull Function | IsError Function | IsNothing Function | IsNumeric Function | IsReference Function | Object Data Type | Date Data Type | TypeName Function

IsDBNull Function

Returns a **Boolean** value indicating whether an expression evaluates to the **System.DBNull** class.

```
Public Function IsDBNull(ByVal Expression As Object) As Boolean
```

Parameter

Expression
Required. **Object** expression.

Remarks

IsDBNull returns **True** if the data type of *Expression* evaluates to the **DBNull** type; otherwise, **IsDBNull** returns **False**.

The **System.DBNull** value indicates that the **Object** represents missing or nonexistent data. **DBNull** is not the same as **Nothing**, which indicates that a variable has not yet been initialized. It is also not the same as a zero-length string (**""**), which is sometimes referred to as a null string.

Example

This example uses the **IsDBNull** function to determine if a variable evaluates to **DBNull**.

```
Dim MyVar As Object
Dim MyCheck As Boolean
MyCheck = IsDBNull(MyVar)   ' Returns False.
MyVar = ""
MyCheck = IsDBNull(MyVar)   ' Returns False.
MyVar = System.DBNull.Value
MyCheck = IsDBNull(MyVar)   ' Returns True.
MsgBox(MyCheck)
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Information

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

IsArray Function | IsDate Function | IsError Function | IsNothing Function | IsNumeric Function | IsReference Function | Object Data Type | DBNull Class | TypeName Function

IsError Function

Returns a **Boolean** value indicating whether an expression is an exception type.

```
Public Function IsError(ByVal Expression As Object) As Boolean
```

Parameter

Expression
Required. **Object** expression.

Remarks

IsError returns **True** if the expression represents an **Object** variable that derives from the **Exception** class in the **System** namespace.

An exception that derives from **System.Exception** can be caught with the **Try...Catch...Finally** statements.

Example

This example uses the **IsError** function to check if an expression represents a system exception.

```
Dim ReturnVal As Object
Dim BadArg As String   ' Name of out-of-range argument.
Dim MyCheck As Boolean
' ...
ReturnVal = New System.ArgumentOutOfRangeException(BadArg)
' ...
MyCheck = IsError(ReturnVal)   ' Returns True.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Information

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

IsArray Function | IsDate Function | IsDBNull Function | IsNothing Function | IsNumeric Function | IsReference Function | Object Data Type | TypeName Function

IsNothing Function

Returns a **Boolean** value indicating whether an expression has no object assigned to it.

```
Public Function IsNothing(ByVal Expression As Object) As Boolean
```

Parameter

Expression
Required. **Object** expression.

Remarks

IsNothing returns **True** if the expression represents an **Object** variable that currently has no object assigned to it; otherwise, it returns **False**.

Example

This example uses the **IsNothing** function to determine if an object variable is associated with any object instance.

```
Dim MyVar As Object   ' No instance assigned to this variable yet.
Dim MyCheck As Boolean
' ...
MyCheck = IsNothing(MyVar)   ' Returns True.
' ...
MyVar = "ABCDEF"   ' Assign a string instance to the variable.
MyCheck = IsNothing(MyVar)   ' Returns False.
' ...
MyVar = Nothing   ' Disassociate the variable from any instance.
MyCheck = IsNothing(MyVar)   ' Returns True.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Information

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

IsArray Function | IsDate Function | IsDBNull Function | IsError Function | IsNumeric Function | IsReference Function | Object Data Type | TypeName Function | Nothing

IsNumeric Function

Returns a **Boolean** value indicating whether an expression can be evaluated as a number.

```
Public Function IsNumeric(ByVal Expression As Object) As Boolean
```

Parameter

Expression
Required. **Object** expression.

Remarks

IsNumeric returns **True** if the entire *Expression* is recognized as a number; otherwise, it returns **False**.

IsNumeric returns **True** if the data type of *Expression* is **Short**, **Integer**, **Long**, **Decimal**, **Single**, or **Short**. It also returns **True** if *Expression* is a **String** that can be successfully converted to a **Double**. It returns **False** if *Expression* is of data type **Date**.

Example

This example uses the **IsNumeric** function to determine if the contents of a variable can be evaluated as a number.

```
Dim MyVar As Object
Dim MyCheck As Boolean
' ...
MyVar = "53"   ' Assign value.
MyCheck = IsNumeric(MyVar)   ' Returns True.
' ...
MyVar = "459.95"   ' Assign value.
MyCheck = IsNumeric(MyVar)   ' Returns True.
' ...
MyVar = "45 Help"   ' Assign value.
MyCheck = IsNumeric(MyVar)   ' Returns False.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Information

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

IsArray Function | IsDate Function | IsDBNull Function | IsError Function | IsNothing Function | IsReference Function | Object Data Type | TypeName Function

IsReference Function

Returns a **Boolean** value indicating whether an expression evaluates to a reference type.

```
Public Function IsReference(ByVal Expression As Object) As Boolean
```

Parameter

Expression
Required. **Object** expression.

Remarks

IsReference returns **True** if the expression represents a reference type, such as a class instance, a **String** type, or an array of any type; otherwise, it returns **False**.

A reference type contains a pointer to data stored elsewhere in memory. A value type contains its own data.

Example

This example uses the **IsReference** function to check if several variables refer to reference types.

```
Dim MyArray(3) As Boolean
Dim MyString As String
Dim MyObject As Object
Dim MyNumber As Integer
MyArray(0) = IsReference(MyArray)   ' Returns True.
MyArray(1) = IsReference(MyString)   ' Returns True.
MyArray(2) = IsReference(MyObject)   ' Returns True.
MyArray(2) = IsReference(MyNumber)   ' Returns False.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Information

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

IsArray Function | IsDate Function | IsDBNull Function | IsError Function | IsNothing Function | IsNumeric Function | Object Data Type | TypeName Function

Join Function

Returns a string created by joining a number of substrings contained in an array.

```
Function Join(
   ByVal SourceArray() As { Object | String },
   Optional ByVal Delimiter As String = " "
) As String
```

Parameters

SourceArray()
Required. One-dimensional array containing substrings to be joined.

Delimiter
Optional. String used to separate the substrings in the returned string. If omitted, the space character (" ") is used. If *Delimiter* is a zero-length string (""), all items in the list are concatenated with no delimiters.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*SourceArray()* is not one dimensional.

Example

The following example demonstrates use of the **Join** function.

```
Dim myItem(2) As String
Dim myShoppingList As String
myItem(0) = "Pickle"
myItem(1) = "Pineapple"
myItem(2) = "Papaya"
' Returns "Pickle, Pineapple, Papaya"
myShoppingList = Join(myItem, ", ")
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Split Function | ArgumentException

Kill Function

Deletes files from a disk.

```
Public Sub Kill(ByVal PathName As String)
```

Parameter

PathName
Required. **String** expression that specifies one or more file names to be deleted. *PathName* may include the directory or folder, and the drive.

Exceptions/Errors

Exception type	Error number	Condition
IOException	55	Target file(s) open.
FileNotFoundException	53	Target file(s) not found.

Remarks

Kill supports the use of multiple-character (*****) and single-character (?) wildcards to specify multiple files.

Example

This example uses the **Kill** function to delete a file from a disk.

```
' Assume TESTFILE is a file containing some data.
Kill("TestFile")   ' Delete file.

' Delete all *.TXT files in current directory.
Kill("*.TXT")
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in MicrosoftVisualBasic.dll)

See Also

RmDir Function | IOException Class | FileNotFoundException Class

LBound Function

Returns the lowest available subscript for the indicated dimension of an array.

```
Public Function LBound( _
   ByVal Array As System.Array, _
   Optional ByVal Rank As Integer = 1 _
) As Integer
```

Parameters

Array
Required. Array of any data type. The array in which you want to find the lowest possible subscript of a dimension.

Rank
Optional. **Integer**. The dimension for which the lowest possible subscript is to be returned. Use 1 for the first dimension, 2 for the second, and so on. If *Rank* is omitted, 1 is assumed.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentNullException	9	*Array* is **Nothing.**
RankException	9	*Rank* < 1 or *Rank* is greater than the rank o f *Array*.

Remarks

Since array subscripts start at 0, the lowest available subscript for every dimension is always 0.

For an array with the following dimensions, **LBound** returns the values in the following table:

```
Dim A(100, 5, 4) As Byte
```

Call to LBound	Return value
`LBound(A, 1)`	0
`LBound(A, 2)`	0
`LBound(A, 3)`	0

Example

This example uses the **LBound** function to determine the lowest available subscript for the indicated dimension of an array.

```
Dim Lowest, MyArray(10, 15, 20), AnyArray(6) as Integer
Lowest = LBound(MyArray, 1)   ' Returns 0.
Lowest = LBound(MyArray, 3)   ' Returns 0.
Lowest = LBound(AnyArray)   ' Returns 0.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Information

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

UBound Function | Dim Statement | ReDim Statement | ArgumentException Class | RankException Class

LCase Function

Returns a string or character converted to lowercase.

```
Public Shared Function LCase(ByVal Value As Char) As Char
```

-or-

```
Public Shared Function LCase(ByVal Value As String) As String
```

Parameter

Value
Required. Any valid **String** or **Char** expression.

Remarks

Only uppercase letters are converted to lowercase; all lowercase letters and nonletter characters remain unchanged.

Example

This example uses the **LCase** function to return a lowercase version of a string.

```
Dim UpperCase, LowerCase As String
Uppercase = "Hello World 1234"   ' String to convert.
Lowercase = LCase(UpperCase)   ' Returns "hello world 1234".
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Strings | String Manipulation | UCase Function

Left Function

Returns a string containing a specified number of characters from the left side of a string.

```
Public Shared Function Left( _
   ByVal Str As String, _
   ByVal Length As Integer _
) As String
```

Parameters

Str
Required. **String** expression from which the leftmost characters are returned.

Length
Required. **Integer** expression. Numeric expression indicating how many characters to return. If 0, a zero-length string ("") is returned. If greater than or equal to the number of characters in *Str*, the entire string is returned.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Length* < 0.

Remarks

To determine the number of characters in *Str*, use the **Len** function. If used in a Windows Form, or any other class that has a **Left** property, you must fully qualify the function with `Microsoft.VisualBasic.Left`.

> **Note** The **LeftB** function in previous versions of Visual Basic returns a string in bytes rather than characters. It is used primarily for converting strings in double-byte character set (DBCS) applications. All Visual Basic .NET strings are in Unicode, and **LeftB** is no longer supported.

Example

This example demonstrates the use of the **Left** function to return a substring of a given **String**. In a class that has a **Left** property, it may be necessary to fully qualify the **Left** function.

```
Dim myString As String = "Hello World!"
Dim subString As String
subString = Microsoft.VisualBasic.Left(myString, 5)   ' Returns "Hello"
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Right Function | Len Function | Mid Function | ArgumentException Class | Programming Element Support Changes Summary

Len Function

Returns an integer containing either the number of characters in a string or the number of bytes required to store a variable.

```
Public Shared Function Len( _
   ByVal Expression As { Boolean | Byte | Char | Double | Integer | Long |
   Object | Short | Single | String | DateTime | Decimal } _
) As Integer
```

Parameters

Expression
Any valid **String** expression or variable name. If *Expression* is of type **Object**, the **Len** function returns the size as it will be written to the file.

Remarks

With user-defined types and **Object** variables, the **Len** function returns the size as it will be written to the file. If an **Object** contains a **String**, it will return the length of the string. If an **Object** contains any other type, it will return the size of the object as it will be written to the file.

> **Note** The **Len** function may not be able to determine the actual number of storage bytes required when used with variable-length strings in user-defined data types.
>
> The **LenB** function in earlier versions of Visual Basic returns the number of bytes in a string rather than characters. It is used primarily for converting strings in double-byte character set (DBCS) applications. All Visual Basic .NET strings are in Unicode, and **LenB** is no longer supported.

Example

This example uses **Len** to return the number of characters in a string.

```
Dim MyString As String
Dim MyLen As Integer
MyString = "Hello World"   ' Initializes variable.
MyLen = Len(MyString)   ' Returns 11.
```

Smart Device Developer Notes

The **Len** function accepts only **String** and **Object** variables as parameters. If an **Object** contains a **String**, it will return the length of the **String**. If a parameter is a NULL **Object** reference, the function returns zero. If an **Object** contains any other type, an exception is thrown.

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Data Type Summary | InStr Function | Programming Element Support Changes Summary

LineInput Function

Reads a single line from an open sequential file and assigns it to a **String** variable.

```
Public Function LineInput(ByVal FileNumber As Integer) As String
```

Parameters

FileNumber
Required. Any valid file number.

Exceptions/Errors

Exception type	Error number	Condition
EndOfStreamException	62	End of file reached.
IOException	52	*FileNumber* does not exist.

Remarks

Data read with **LineInput** is usually written to a file with **Print**.

> **Security Note** When reading from files, do not make decisions about the contents of a file based on the file name extension. For example, a file named Form1.vb may not be a Visual Basic .NET source file.

The **LineInput** function reads from a file one character at a time until it encounters a carriage return (**Chr(**13**)**) or carriage return–linefeed (**Chr(**13**)** + **Chr(**10**)**) sequence. Carriage return–linefeed sequences are skipped rather than appended to the character string.

> **Security Note** Reading from a file with the **LineInput** function requires **Read** assess from the **FileIOPermissionAccess** enumeration. For more information, see FileIOPermissionAccess Enumeration.

Example

This example uses the **LineInput** function to read a line from a sequential file and assign it to a variable. This example assumes that `TESTFILE` is a text file with a few lines of sample data.

```
Dim TextLine As String
FileOpen(1, "TESTFILE", OpenMode.Input)   ' Open file.
While Not EOF(1)   ' Loop until end of file.
   TextLine = LineInput(1)   ' Read line into variable.
   Debug.WriteLine(TextLine)   ' Print to the console.
End While
FileClose(1)   ' Close file.
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Chr, ChrW Functions | Input Function | EndOfStreamException Class | IOException Class

Loc Function

Returns a **Long** value specifying the current read/write position within an open file.

```
Public Function Loc(ByVal FileNumber As Integer) As Long
```

Parameter

FileNumber
Required. Any valid **Integer** file number.

Exceptions/Errors

Exception type	Error number	Condition
IOException	52	*FileNumber* does not exist.
IOException	54	File mode is invalid.

Remarks

The following describes the return value for each file access mode:

Mode	Return value
Random	Number of the last record read from or written to the file.
Sequential	Current byte position in the file divided by 128. However, information returned by **Loc** for sequential files is neither used nor required.
Binary	Position of the last byte read or written.

Example

This example uses the **Loc** function to return the current read/write position within an open file. This example assumes that `MYFILE` is a text file with a few lines of sample data.

```
Dim location As Long
Dim oneLine As String
Dim oneChar As Char
FileOpen(1, "C:\MYFILE.TXT", OpenMode.Binary)
While location < EOF(1)
   Input(1, oneChar)
   location = Loc(1)
   Debug.WriteLine(location & ControlChars.CrLf)
End While
FileClose(1)
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

EOF Function | LOF Function | Seek Function | File Access with Visual Basic Run-Time Functions | IOException Class

Lock, Unlock Functions

Controls access by other processes to all or part of a file opened using the **Open** function.

```
Public Overloads Sub Lock(ByVal FileNumber As Integer)
. . .
Public Overloads Sub Unlock(ByVal FileNumber As Integer)
```

-or-

```
Public Overloads Sub Lock(_
   ByVal FileNumber As Integer, _
   ByVal FromRecord As Long _
)
. . .
Public Overloads Sub Unlock( _
   ByVal FileNumber As Integer, _
   ByVal FromRecord As Long _
)
```

-or-

```
Public Overloads Sub Lock( _
   ByVal FileNumber As Integer, _
   ByVal FromRecord As Long, _
   ByVal ToRecord As Long _
)
. . .
Public Overloads Sub Unlock( _
   ByVal FileNumber As Integer, _
   ByVal FromRecord As Long, _
   ByVal ToRecord As Long _
)
```

Parameters

FileNumber
Required. Any valid file number.
FromRecord
Optional. Number of the first record or byte to lock or unlock.
ToRecord
Optional. Number of the last record or byte to lock or unlock.

Exceptions/Errors

Exception type	Error number	Condition
IOException	52	*FileNumber* does not exist.
IOException	54	File mode is invalid.

Remarks

The **Lock** and **Unlock** functions are used in environments where several processes might need access to the same file.

Lock and **Unlock** functions are always used in pairs. The arguments to **Lock** and **Unlock** must match exactly.

If *FromRecord* and *ToRecord* are not supplied, the lock will be for the entire file. If *FromRecord* is specified but not *ToRecord*, the single record will be locked/unlocked.

If the file has been opened for sequential input or output, **Lock** and **Unlock** affect the entire file, regardless of the range specified by *FromRecord* and *ToRecord*.

Example

This example illustrates the use of the **Lock** and **Unlock** functions. This example assumes that `people.txt` is a file containing records of the structure `Person`.

```
Structure Person
   Dim Name As String
   Dim ID As Integer
End Structure

Sub PutInLockedFile(ByVal index As Integer, ByVal onePerson As Person)
   Try
      FileOpen(1, "c:\people.txt", OpenMode.Binary)
      Lock(1)
      FilePut(index, onePerson)
      Unlock(1)
      FileClose(1)
   Catch
      ' Error recovery code here.
   End Try
End Sub
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

FileOpen Function | IOException Class

LOF Function

Returns a **Long** representing the size, in bytes, of a file opened using the **FileOpen** function.

```
Public Function LOF(ByVal FileNumber As Integer) As Long
```

Parameter

FileNumber
Required. An **Integer** containing a valid file number.

Exceptions/Errors

Exception type	Error number	Condition
IOException	52	*FileNumber* does not exist.
IOException	54	File mode is invalid.

Remarks

Use the **FileLen** function to obtain the length of a file that is not open.

Example

This example uses the **LOF** function to determine the size of an open file. This example assumes that `TESTFILE` is a text file containing sample data.

```
Dim length As Integer
FileOpen(1, "C:\TESTFILE.TXT", OpenMode.Input) ' Open file.
length = LOF(1)   ' Get length of file.
Debug.WriteLine(length)
FileClose(1)   ' Close file.
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

EOF Function | FileLen Function | Loc Function | FileOpen Function | IOException Class

Math Functions

The math functions in Visual Basic 6 have been replaced by equivalent methods in the **System.Math** class of the .NET Framework.

Remarks

The .NET Framework math methods are functionally identical to their Visual Basic 6 counterparts, although some have slightly different names. For example, the .NET Framework equivalent of the Visual Basic 6 Atn function is **Atan**. The following table lists the Visual Basic 6 math function names and the equivalent .NET Framework methods.

Visual Basic 6 function	Visual Basic .NET method	Description
Abs	Math.Abs Method	Returns the absolute value of a specified number.
Atn	Math.Atan Method	Returns a **Double** value containing the angle whose tangent is the specified number.
Cos	Math.Cos Method	Returns a **Double** value containing the cosine of the specified angle.
Exp	Math.Exp Method	Returns a **Double** value containing e (the base of natural logarithms) raised to the specified power.
Log	Math.Log Method	Returns a **Double** value containing the logarithm of a specified number. This method is overloaded and can return either the natural (base e) logarithm of a specified number or the logarithm of a specified number in a specified base.
Round	Math.Round Method	Returns a **Double** value containing the number nearest the specified value. Additional round functions are available as methods of the intrinsic types such as Decimal.Round Method.
Sgn	Math.Sign Method	Returns an **Integer** value indicating the sign of a number.
Sin	Math.Sin Method	Returns a **Double** value specifying the sine of an angle.
Sqr	Math.Sqrt Method	Returns a **Double** value specifying the square root of a number.
Tan	Math.Tan Method	Returns a **Double** value containing the tangent of an angle.

In addition, the .NET Framework math class provides constants and other static methods for trigonometric, logarithmic, and other common mathematical functions. All of these can be used in a Visual Basic program.

To use these functions without qualification, import the **System.Math** namespace into your project by adding the following code to the top of the source code:

```
Imports System.Math
```

Requirements

Class: Math Class

Abs Example

This example uses the **Abs** method of the **Math** class to compute the absolute value of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyNumber As Double
```

```
MyNumber = Abs(50.3)    ' Returns 50.3.
MyNumber = Abs(-50.3)   ' Returns 50.3.
```

Atan Example

This example uses the **Atan** method of the **Math** class to calculate the value of pi.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim pi As Double
pi = 4 * Atan(1)   ' Calculate the value of pi.
```

Cos Example

This example uses the **Cos** method of the **Math** class to return the cosine of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MySecant As Double
MyAngle = 1.3   ' Define angle in radians.
MySecant = 1 / Cos(MyAngle)   ' Calculate secant.
```

Exp Example

This example uses the **Exp** method of the **Math** class to return *e* raised to a power.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyHSin As Double
' Define angle in radians.
MyAngle = 1.3
' Calculate hyperbolic sine.
MyHSin = (Exp(MyAngle) - Exp(-1 * MyAngle)) / 2
```

Log Example

This example uses the **Log** method of the **Math** class to return the natural logarithm of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyLog As Double
' Define angle in radians.
MyAngle = 1.3
' Calculate inverse hyperbolic sine.
MyLog = Log(MyAngle + Sqrt(MyAngle * MyAngle + 1))
```

Round Example

This example uses the **Round** method of the **Math** class to round a number to the nearest integer.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyVar1 As Double = 2.8
Dim MyVar2 As Double
MyVar2 =Round(MyVar1)   ' Returns 3.
```

Sign Example

This example uses the **Sign** method of the **Math** class to determine the sign of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyVar1, MyVar2, MyVar3 As Double
Dim MySign As Integer
MyVar1 = 12
MyVar2 = -2.4
MyVar3 = 0
MySign = Sign(MyVar1)   ' Returns 1.
MySign = Sign(MyVar2)   ' Returns -1.
MySign = Sign(MyVar3)   ' Returns 0.
```

Sin Example

This example uses the **Sin** method of the **Math** class to return the sine of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyCosecant As Double
MyAngle = 1.3   ' Define angle in radians.
MyCosecant = 1 / Sin(MyAngle)   ' Calculate cosecant.
```

Sqrt Example

This example uses the **Sqrt** method of the **Math** class to calculate the square root of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MySqr As Double
MySqr = Sqrt(4)    ' Returns 2.
MySqr = Sqrt(23)   ' Returns 4.79583152331272.
MySqr = Sqrt(0)    ' Returns 0.
MySqr = Sqrt(-4)   ' Returns NaN (not a number).
```

Tan Example

This example uses the **Tan** method of the **Math** class to return the tangent of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyCotangent As Double
MyAngle = 1.3   ' Define angle in radians.
MyCotangent = 1 / Tan(MyAngle)   ' Calculate cotangent.
```

Requirements

Namespace: System.Math

Assembly: mscorlib (in mscorlib.dll)

See Also

Rnd Function | Randomize Statement | Derived Math Functions | Double.NaN Field

LSet Function

Returns a left-aligned string containing the specified string adjusted to the specified length.

```
Public Shared Function LSet( _
   ByVal Source As String, _
   ByVal Length As Integer _
) As String
```

Parameters

Source
Required. **String** expression. Name of string variable.
Length
Required. **Integer** expression. Length of returned string.

Remarks

If the specified string is longer than the specified length, the returned string is shortened to the specified length. If the specified string is shorter than the specified length, spaces are added to the right end of the returned string to produce the appropriate length.

Example

This example demonstrates the use of the **LSet** function.

```
Dim myString As String = "Left"
Dim lString As String
LString = LSet(myString, 10)   ' Returns "Left      "
LString = LSet(myString, 2)    ' Returns "Le"
LString = LSet(myString, 4)    ' Returns "Left"
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Data Type Summary | RSet Function | Efficient Use of Data Types

LTrim, RTrim, and Trim Functions

Returns a string containing a copy of a specified string with no leading spaces (**LTrim**), no trailing spaces (**RTrim**), or no leading or trailing spaces (**Trim**).

```
Public Shared Function LTrim(ByVal Str As String) As String
Public Shared Function RTrim(ByVal Str As String) As String
Public Shared Function Trim(ByVal Str As String) As String
```

Parameter

Str
Required. Any valid **String** expression.

Example

This example uses the **LTrim** function to strip leading spaces and the **RTrim** function to strip trailing spaces from a string variable. It uses the **Trim** function to strip both types of spaces.

```
Dim MyString, TrimString As String
MyString = "  <-Trim->  "   ' Initializes string.
TrimString = LTrim(MyString)   ' TrimString = "<-Trim->  ".
TrimString = RTrim(MyString)   ' TrimString = "  <-Trim->".
TrimString = LTrim(RTrim(MyString))   ' TrimString = "<-Trim->".
' Using the Trim function alone achieves the same result.
TrimString = Trim(MyString)   ' TrimString = "<-Trim->".
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Left Function | Right Function

M-R Functions

The following table contains a listing of the Visual Basic .NET run-time member functions.

Mid	Minute	MIRR	MkDir
Month	MonthName	MsgBox	NPer
NPV	Oct	Partition	Pmt
PPmt	Print	PrintLine	PV
QBColor	Rate	Rename	Replace
Reset	RGB	Right	RmDir
Rnd	Round	RSet	RTrim

See Also

A-C Functions | D-G Functions | H-L Functions | S-Z Functions | Visual Basic Language and Run-Time Reference

Mid Function

Returns a string containing a specified number of characters from a string.

```
Public Shared Function Mid( _
   ByVal Str As String, _
   ByVal Start As Integer, _
   Optional ByVal Length As Integer _
) As String
```

Parameters

Str
Required. **String** expression from which characters are returned.

Start
Required. **Integer** expression. Character position in *Str* at which the part to be taken starts. If *Start* is greater than the number of characters in *Str*, the **Mid** function returns a zero-length string (""). *Start* is one based.

Length
Optional. **Integer** expression. Number of characters to return. If omitted or if there are fewer than *Length* characters in the text (including the character at position *Start*), all characters from the start position to the end of the string are returned.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Start* <= 0 or *Length* < 0 .

Remarks

To determine the number of characters in *Str*, use the **Len** function.

> **Note** The **MidB** function in previous versions of Visual Basic returns a string in bytes rather than characters. It is used primarily for converting strings in double-byte character set (DBCS) applications. All Visual Basic .NET strings are in Unicode, and **MidB** is no longer supported.

Example

This example uses the **Mid** function to return a specified number of characters from a string.

```
Dim MyString, FirstWord, LastWord, MidWords As String
MyString = "Mid Function Demo"   ' Creates text string.
FirstWord = Mid(MyString, 1, 3)   ' Returns "Mid".
LastWord = Mid(MyString, 14, 4)   ' Returns "Demo".
MidWords = Mid(MyString, 5)   ' Returns "Function Demo".
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Strings | String Manipulation | Left Function | Len Function | LTrim, RTrim, and Trim Functions | Mid Statement | Right Function | ArgumentException Class | Programming Element Support Changes Summary

Minute Function

Returns an **Integer** value from 0 through 59 representing the minute of the hour.

```
Public Function Minute(ByVal TimeValue As DateTime) As Integer
```

Parameter

TimeValue
Required. **Date** value from which you want to extract the minute.

You can also obtain the minute of the hour by calling **DatePart** and specifying **DateInterval.Minute** for the *Interval* argument.

Example

This example uses the **Minute** function to obtain the minute of the hour from a specified time. In the development environment, the time literal is displayed in short time format using the locale settings of your code.

```
Dim MyTime As Date
Dim MyMinute As Integer
MyTime = #4:35:17 PM#   ' Assign a time.
MyMinute = Minute(MyTime)   ' MyMinute contains 35.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: DateAndTime

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Day Function | Hour Function | Now Property | Second Function | TimeOfDay Property | DatePart Function System Namespace | DateTime Structure | ArgumentException Class | ArgumentOutOfRangeException Class

MIRR Function

Returns a **Double** specifying the modified internal rate of return for a series of periodic cash flows (payments and receipts).

```
Function MIRR( _
   ByRef ValueArray() As Double, _
   ByVal FinanceRate As Double, _
   ByVal ReinvestRate As Double _
) As Double
```

Parameters

ValueArray()
Required. Array of **Double** specifying cash flow values. The array must contain at least one negative value (a payment) and one positive value (a receipt).

FinanceRate
Required. **Double** specifying interest rate paid as the cost of financing.

ReinvestRate
Required. **Double** specifying interest rate received on gains from cash reinvestment.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	Rank of *ValueArray* does not equal 1 .
ArgumentException	5	*FinanceRate* = -1
ArgumentException	5	*ReinvestRate* = -1
DivideByZeroException	11	Division by zero has occurred.

Remarks

The modified internal rate of return is the internal rate of return when payments and receipts are financed at different rates. The **MIRR** function takes into account both the cost of the investment (*FinanceRate*) and the interest rate received on reinvestment of cash (*ReinvestRate*).

The *FinanceRate* and *ReinvestRatearguments* are percentages expressed as decimal values. For example, 12 percent is expressed as 0.12.

The **MIRR** function uses the order of values within the array to interpret the order of payments and receipts. Be sure to enter your payment and receipt values in the correct sequence.

Example

This example uses the **MIRR** function to return the modified internal rate of return for a series of cash flows contained in the array `Values()`. `LoanAPR` represents the financing interest, and `InvAPR` represents the interest rate received on reinvestment.

```
Sub TestMIRR()
   Dim LoanAPR, InvAPR, RetRate, Values(4) As Double
   Dim Msg, Fmt As String
   LoanAPR = 0.1  ' Loan rate.
   InvAPR = 0.12  ' Reinvestment rate.
   Fmt = "#0.00"   ' Define money format.
   Values(0) = -70000   ' Business start-up costs.
   ' Positive cash flows reflecting income for four successive years.
   Values(1) = 22000 : Values(2) = 25000
   Values(3) = 28000 : Values(4) = 31000
   RetRate = MIRR(Values, LoanAPR, InvAPR)   ' Calculate internal rate.
   Msg = "The modified internal rate of return for these five cash flows is "
   Msg = Msg & Format(Math.Abs(RetRate) * 100, CStr(Fmt)) & "%."
   MsgBox(Msg)    ' Display internal return rate.
End Sub
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Financial

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

MkDir Function

Creates a new directory or folder.

```
Public Sub MkDir(ByVal Path As String)
```

Parameter

Path
Required. **String** expression that identifies the directory or folder to be created. The *Path* may include the drive. If no drive is specified, **MkDir** creates the new directory or folder on the current drive.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	52	*Path* is not specified or is empty .
IOException	75	Directory already exists.

Example

This example uses the **MkDir** function to create a directory or folder. If the drive is not specified, the new directory or folder is created on the current drive.

```
MkDir("C:\MYDIR")   ' Make new directory or folder.
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in MicrosoftVisualBasic.dll)

See Also

ChDir Function | CurDir Function | RmDir Function | ArgumentException Class| IOException Class

Month Function

Returns an **Integer** value from 1 through 12 representing the month of the year.

```
Public Function Month(ByVal DateValue As DateTime) As Integer
```

Parameter

DateValue
Required. **Date** value from which you want to extract the month.

You can also obtain the month of the year by calling **DatePart** and specifying **DateInterval.Month** for the *Interval* argument.

Example

This example uses the **Month** function to obtain the month from a specified date. In the development environment, the date literal is displayed in short date format using the locale settings of your code.

```
Dim MyDate As Date
Dim MyMonth As Integer
MyDate = #2/12/1969#   ' Assign a date.
MyMonth = Month(MyDate)   ' MyMonth contains 2.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: DateAndTime

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Day Function | Now Property | Weekday Function | Year Function | DatePart Function | System Namespace | DateTime Structure | ArgumentException Class | ArgumentOutOfRangeException Class

MonthName Function

Returns a **String** value containing the name of the specified month.

```
Public Function MonthName( _
   ByVal Month As Integer, _
   Optional ByVal Abbreviate As Boolean = False _
) As String
```

Parameters

Month
Required. **Integer**. The numeric designation of the month, from 1 through 13; 1 indicates January and 12 indicates December. You can use the value 13 with a 13-month calendar. If your system is using a 12-month calendar and *Month* is 13, **MonthName** returns an empty string.

Abbreviate
Optional. **Boolean** value that indicates if the month name is to be abbreviated. If omitted, the default is **False**, which means the month name is not abbreviated.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Month* is less than 1 or greater than 13 .

Remarks

The string returned by **MonthName** depends not only on the input arguments, but also on the Regional Options settings specified in the Windows Control Panel.

If *Month* is less than 1 or more than 13, an **ArgumentException** error occurs.

> **Note** **MonthName** uses the current calendar setting from the **CurrentCulture** property of the **CultureInfo** class in the **System.Globalization** namespace. The default **CurrentCulture** values are determined by **Control Panel** settings.

Example

This example uses the **MonthName** function to determine the name of the month, by the integer given. The Boolean value will determine whether the full name (**False**) or the abbreviated name (**True**) will be displayed.

```
Dim MyMonth As Integer
Dim Name As String
MyMonth = 4
Name = MonthName(MyMonth, True)   ' "True" returns an abbreviated name.
Msgbox(Name)   ' Name contains "Apr".
```

Requirements

Namespace: Microsoft.VisualBasic

Module: DateAndTime

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

WeekdayName Function | System Namespace | System.Globalization Namespace | DateTime Structure | ArgumentException Class | CultureInfo Class

MsgBox Function

Displays a message in a dialog box, waits for the user to click a button, and then returns an integer indicating which button the user clicked.

```
Public Function MsgBox( _
   ByVal Prompt As Object, _
   Optional ByVal Buttons As MsgBoxStyle = MsgBoxStyle.OKOnly, _
   Optional ByVal Title As Object = Nothing _
) As MsgBoxResult
```

Parameters

Prompt
Required. **String** expression displayed as the message in the dialog box. The maximum length of *Prompt* is approximately 1024 characters, depending on the width of the characters used. If *Prompt* consists of more than one line, you can separate the lines using a carriage return character (**Chr(**13**)**), a linefeed character (**Chr(**10**)**), or a carriage return/linefeed character combination (**Chr(**13**)** & **Chr(**10**)**) between each line.

Buttons
Optional. Numeric expression that is the sum of values specifying the number and type of buttons to display, the icon style to use, the identity of the default button, and the modality of the message box. If you omit *Buttons*, the default value is zero.

Title
Optional. **String** expression displayed in the title bar of the dialog box. If you omit *Title*, the application name is placed in the title bar.

Settings

The **MsgBoxStyle** enumeration values are listed in the following table.

Enumeration	Value	Description
OKOnly	0	Displays OK button only.
OKCancel	1	Displays OK and Cancel buttons.
AbortRetryIgnore	2	Displays Abort, Retry, and Ignore buttons.
YesNoCancel	3	Displays Yes, No, and Cancel buttons.
YesNo	4	Displays Yes and No buttons.
RetryCancel	5	Displays Retry and Cancel buttons.
Critical	16	Displays Critical Message icon.
Question	32	Displays Warning Query icon.
Exclamation	48	Displays Warning Message icon.
Information	64	Displays Information Message icon.
DefaultButton1	0	First button is default.
DefaultButton2	256	Second button is default.
DefaultButton3	512	Third button is default.
ApplicationModal	0	Application is modal. The user must respond to the message box b efore continuing work in the current application.
SystemModal	4096	System is modal. All applications are suspended until the user resp onds to the message box.
MsgBoxSetForeground	65536	Specifies the message box window as the foreground window.
MsgBoxRight	524288	Text is right-aligned.
MsgBoxRtlReading	1048576	Specifies text should appear as right-to-left reading on Hebrew an d Arabic systems.

The first group of values (0–5) describes the number and type of buttons displayed in the dialog box; the second group (16, 32, 48, 64) describes the icon style; the third group (0, 256, 512) determines which button is the default; the fourth group (0, 4096) determines the modality of the message box, and the fifth group specifies whether or not the message box window is the foreground window, along with the alignment and direction of the text. When adding numbers to create a final value for the *Buttons* argument, use only one number from each group.

Return Values

Constant	Value
OK	1
Cancel	2
Abort	3
Retry	4
Ignore	5
Yes	6
No	7

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Prompt* is not a **String** expression, or *Title* is invalid.
InvalidOperationException	5	Process is not running in User Interactive mode.
InvalidEnumArgumentException	5	One or more parameters not a member of **MsgBoxResult** or **MsgBoxStyle** enumerations.

Remarks

If the dialog box displays a **Cancel** button, pressing the ESC key has the same effect as clicking **Cancel**. If the dialog box contains a **Help** button, context-sensitive Help is provided for the dialog box. However, no value is returned until one of the other buttons is clicked.

> **Note** To specify more than the first argument, you must use the **MsgBox** function in an expression. If you omit any positional arguments, you must retain the corresponding comma delimiter.
>
> **Note** The **MsgBox** function requires UIPermission at the SafeTopLevelWindows level, which may affect its execution in partial trust situations. For more information, see Requesting Permissions and UIPermission Class.

Example

This example uses the **MsgBox** function to display a critical-error message in a dialog box with Yes and No buttons. The No button is specified as the default response. This is done by combining the **MsgBox** constant values into one numeric expression. In this case, adding 4 (the Yes/No button combination) and 16 (the Critical Message window) and 256 (the second button as default button) gives a total of 276. The value returned by the **MsgBox** function depends on the button chosen by the user: Yes returns a value of 6; No returns a value of 7.

```
Dim msg As String
Dim title As String
Dim style As MsgBoxStyle
Dim response As MsgBoxResult
msg = "Do you want to continue?"   ' Define message.
style = MsgBoxStyle.DefaultButton2 Or _
   MsgBoxStyle.Critical Or MsgBoxStyle.YesNo
title = "MsgBox Demonstration"   ' Define title.
' Display message.
response = MsgBox(msg, style, title)
If response = MsgBoxResult.Yes Then   ' User chose Yes.
   ' Perform some action.
Else
   ' Perform some other action.
End If
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Interaction

Assembly: Microsoft.Visual Basic .NET Runtime (in MicrosoftVisualBasic.dll)

See Also

InputBox Function

NPer Function

Returns a **Double** specifying the number of periods for an annuity based on periodic, fixed payments and a fixed interest rate.

```
Function NPer( _
    ByVal Rate As Double, _
   ByVal Pmt As Double, _
   ByVal PV As Double, _
   Optional ByVal FV As Double = 0, _
   Optional ByVal Due As DueDate = DueDate.EndOfPeriod _
) As Double
```

Parameters

Rate
Required. **Double** specifying interest rate per period. For example, if you get a car loan at an annual percentage rate (APR) of 10 percent and make monthly payments, the rate per period is 0.1/12, or 0.0083.

Pmt
Required. **Double** specifying payment to be made each period. Payments usually contain principal and interest that doesn't change over the life of the annuity.

PV
Required. **Double** specifying present value, or value today, of a series of future payments or receipts. For example, when you borrow money to buy a car, the loan amount is the present value to the lender of the monthly car payments you will make.

FV
Optional. **Double** specifying future value or cash balance you want after you've made the final payment. For example, the future value of a loan is $0 because that's its value after the final payment. However, if you want to save $50,000 over 18 years for your child's education, then $50,000 is the future value. If omitted, 0 is assumed.

Due
Optional. Object of type `Microsoft.VisualBasic.DueDate` that specifies when payments are due. This argument must be either `DueDate.EndOfPeriod` if payments are due at the end of the payment period, or `DueDate.BegOfPeriod` if payments are due at the beginning of the period. If omitted, `DueDate.EndOfPeriod` is assumed.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Rate* <= -1.
ArgumentException	5	*Rate* = 0 and *Pmt* = 0

Remarks

An annuity is a series of fixed cash payments made over a period of time. An annuity can be a loan (such as a home mortgage) or an investment (such as a monthly savings plan).

For all arguments, cash paid out (such as deposits to savings) is represented by negative numbers; cash received (such as dividend checks) is represented by positive numbers.

Example

This example uses the **NPer** function to return the number of periods during which payments must be made to pay off a loan whose value is contained in `PVal`. Also provided are the interest percentage rate per period (`APR / 12`), the payment (`Payment`), the future value of the loan (`FVal`), and a number that indicates whether the payment is due at the beginning or end of the payment period (`PayType`).

```
Sub TestNPer()
   Dim FVal, TotPmts As Double
   Dim PVal, APR, Payment As Double
   Dim PayType As DueDate
   Dim Response As MsgBoxResult
   FVal = 0   ' Usually 0 for a loan.
   PVal = CDbl(InputBox("How much do you want to borrow?"))
```

```
    APR = CDbl(InputBox("What is the annual percentage rate of your loan?"))
    If APR > 1 Then APR = APR / 100 ' Ensure proper form.
    Payment = CDbl(InputBox("How much do you want to pay each month?"))
    Response = MsgBox("Do you make payments at the end of month?", MsgBoxStyle.YesNo)
    If Response = MsgBoxResult.No Then
       PayType = DueDate.BegOfPeriod
    Else
       PayType = DueDate.EndOfPeriod
    End If
    TotPmts = NPer(APR / 12, -Payment, PVal, FVal, PayType)
    If Int(TotPmts) <> TotPmts Then TotPmts = Int(TotPmts) + 1
       MsgBox("It will take you " & TotPmts & " months to pay off your loan.")
End Sub
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Financial

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

DDB Function | FV Function | IPmt Function | IRR Function | MIRR Function | NPV Function | Pmt Function | PPmt Function | PV Function | Rate Function | SLN Function | SYD Function | ArgumentException Class

NPV Function

Returns a **Double** specifying the net present value of an investment based on a series of periodic cash flows (payments and receipts) and a discount rate.

```
Function NPV( _
   ByVal Rate As Double, _
   ByRef ValueArray() As Double _
) As Double
```

Parameters

Rate
Required. **Double** specifying discount rate over the length of the period, expressed as a decimal.

ValueArray()
Required. Array of **Double** specifying cash flow values. The array must contain at least one negative value (a payment) and one positive value (a receipt).

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*ValueArray* is **Nothing,** rank of *ValueArray* <> 1, or *Rate* = -1

Remarks

The net present value of an investment is the current value of a future series of payments and receipts.

The **NPV** function uses the order of values within the array to interpret the order of payments and receipts. Be sure to enter your payment and receipt values in the correct sequence.

The **NPV** investment begins one period before the date of the first cash flow value and ends with the last cash flow value in the array.

The net present value calculation is based on future cash flows. If your first cash flow occurs at the beginning of the first period, the first value must be added to the value returned by **NPV** and must not be included in the cash flow values of *ValueArray()*.

The **NPV** function is similar to the **PV** function (present value) except that the **PV** function allows cash flows to begin either at the end or the beginning of a period. Unlike the variable **NPV** cash flow values, **PV** cash flows must be fixed throughout the investment.

Example

This example uses the **NPV** function to return the net present value for a series of cash flows contained in the array `Values()`. `RetRate` represents the fixed internal rate of return.

```
Sub TestNPV()
   Dim Guess, RetRate, NetPVal, values(4) As Double
   Dim Fmt, Msg As String
   Fmt = "###,##0.00"   ' Define money format.
   Guess = 0.1  ' Guess starts at 10 percent.
   RetRate = 0.0625  ' Set fixed internal rate.
   values(0) = -70000   ' Business start-up costs.
   ' Positive cash flows reflecting income for four successive years.
   values(1) = 22000 : values(2) = 25000
   values(3) = 28000 : values(4) = 31000
   NetPVal = NPV(RetRate, values)   ' Calculate net present value.
   Msg = "The net present value of these cash flows is "
   Msg = Msg & Format(NetPVal, Fmt) & "."
   MsgBox(Msg)    ' Display net present value.
End Sub
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Financial

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Oct Function

Returns a string representing the octal value of a number.

```
Public Shared Function Oct( _
   ByVal Number As { Byte | Short | Integer | Long | Object } _
) As String
```

Parameter

Number
Required. Any valid numeric expression or **String** expression.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentNullException	5	*Number* is not specified.
ArgumentException	5	*Number* is not a numeric type.

Remarks

If *Number* is not already a whole number, it is rounded to the nearest whole number before being evaluated.

If *Number* is	Oct returns
Empty	Zero (0)
Any other number	Up to 22 octal characters

You can represent octal numbers directly by preceding numbers in the proper range with **&O**. For example, `&O10` is the octal notation for decimal 8.

Example

This example uses the **Oct** function to return the octal value of a number.

```
Dim MyOct As String
MyOct = Oct(4)    ' Returns 4.
MyOct = Oct(8)   ' Returns 10.
MyOct = Oct(459)   ' Returns 713.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Conversion

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Hex Function | Type Conversion Functions | ArgumentNullException Class

Partition Function

Returns a string representing the calculated range that contains a number.

```
Public Function Partition( _
   ByVal Number As Long, _
   ByVal Start As Long, _
   ByVal Stop As Long, _
   ByVal Interval As Long _
) As String
```

Parameters

Number
Required. **Long**. Whole number that you want to locate within one of the calculated ranges.
Start
Required. **Long**. Whole number that indicates the start of the set of calculated ranges. *Start* cannot be less than 0.
Stop
Required. **Long**. Whole number that indicates the end of the set of calculated ranges. *Stop* cannot be less than or equal to *Start*.
Interval
Required. **Long**. Whole number that indicates the size of each range calculated between *Start* and *Stop*. *Interval* cannot be less than 1.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Start* < 0, *Stop* <= *Start*, or *Interval* < 1 .

Remarks

The **Partition** function calculates a set of numeric ranges, each containing the number of values specified by *Interval*. The first range begins at *Start*, and the last range ends at *Stop*. The **Partition** function then identifies which range contains *Number* and returns a string describing that range. The range is represented in the string as "*lowervalue*:*uppervalue*", where the low end of the range (*lowervalue*) is separated from the high end (*uppervalue*) by a colon (:).

If necessary, the **Partition** function inserts leading spaces before *lowervalue* and *uppervalue* so that they both have the same number of characters as the string representation of the value (*Stop* + 1). This ensures that if you use the output of the **Partition** function with several values of *Number*, the resulting text will be handled properly during any subsequent sort operation.

The following table shows some sample strings for ranges calculated using three sets of *Start*, *Stop*, and *Interval*. The "First range" and "Last range" columns show the lowest and highest ranges possible given the values of *Start* and *Stop*. The "Before first range" and "After last range" columns show the strings returned for values of *Number* less than *Start* and greater than *Stop*, respectively.

Start	***Stop***	***Interval***	**Before first range**	**First range**	**Last range**	**After last range**
0	99	5	" : -1"	" 0: 4"	" 95: 99"	"100: "
20	199	10	" : 19"	" 20: 29"	"190:199"	"200: "
100	1010	20	" : 99"	" 100: 119"	"1000:1010"	"1011: "

In the preceding table, the third line shows the result when *Start* and *Stop* define a set of numbers that cannot be evenly divided by *Interval*. The last range ends at *Stop*, making it only 11 numbers long, even though *Interval* is 20.

If *Interval* is 1, the range is "*Number*:*Number*", regardless of the *Start* and *Stop* arguments. For example, if *Number* is 267, *Stop* is 1000, and *Interval* is 1, **Partition** returns " 267: 267".

Partition is useful in database queries. You can create a select query that shows how many orders occur within various value ranges, for example with invoice values from 1 to 1000, 1001 to 2000, and so on.

Example

This example assumes you have an **Orders** table that contains a `Freight` field. It creates a SELECT procedure that counts the number of orders for which freight cost is within each of several ranges. The **Partition** function first establishes these ranges, and

then the SQL **Count** function counts the number of orders in each range. In this example, the arguments to the **Partition** function are *Start* = 0, *Stop* = 500, *Interval* = 50. The first range is therefore 0:49, and so on up to 450:499 and 500:500.

```
SELECT DISTINCTROW Partition([Freight],0, 500, 50) As Range,
Count(Orders.Freight) As Count
FROM Orders
GROUP BY Partition([Freight],0,500,50);
```

SQL

Pmt Function

Returns a **Double** specifying the payment for an annuity based on periodic, fixed payments and a fixed interest rate.

```
Function Pmt( _
   ByVal Rate As Double, _
   ByVal NPer As Double, _
   ByVal PV As Double, _
   Optional ByVal FV As Double = 0, _
   Optional ByVal Due As DueDate = DueDate.EndOfPeriod _
) As Double
```

Parameters

Rate
Required. **Double** specifying interest rate per period. For example, if you get a car loan at an annual percentage rate (APR) of 10 percent and make monthly payments, the rate per period is 0.1/12, or 0.0083.

NPer
Required. **Double** specifying total number of payment periods in the annuity. For example, if you make monthly payments on a four-year car loan, your loan has a total of 4 * 12 (or 48) payment periods.

PV
Required. **Double** specifying present value (or lump sum) that a series of payments to be paid in the future is worth now. For example, when you borrow money to buy a car, the loan amount is the present value to the lender of the monthly car payments you will make.

FV
Optional. **Double** specifying future value or cash balance you want after you've made the final payment. For example, the future value of a loan is $0 because that's its value after the final payment. However, if you want to save $50,000 over 18 years for your child's education, then $50,000 is the future value. If omitted, 0 is assumed.

Due
Optional. Object of type `Microsoft.VisualBasic.DueDate` that specifies when payments are due. This argument must be either `DueDate.EndOfPeriod` if payments are due at the end of the payment period, or `DueDate.BegOfPeriod` if payments are due at the beginning of the period. If omitted, `DueDate.EndOfPeriod` is assumed.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*NPer* = 0.

Remarks

An annuity is a series of fixed cash payments made over a period of time. An annuity can be a loan (such as a home mortgage) or an investment (such as a monthly savings plan).

The *Rate* and *NPer* arguments must be calculated using payment periods expressed in the same units. For example, if *Rate* is calculated using months, *NPer* must also be calculated using months.

For all arguments, cash paid out (such as deposits to savings) is represented by negative numbers; cash received (such as dividend checks) is represented by positive numbers.

Example

This example uses the **Pmt** function to return the monthly payment for a loan over a fixed period. Given are the interest percentage rate per period (`APR / 12`), the total number of payments (`TotPmts`), the present value or principal of the loan (`PVal`), the future value of the loan (`FVal`), and a number that indicates whether the payment is due at the beginning or end of the payment period `(PayType)`.

```
Sub TestPMT()
   Dim PVal, APR, FVal, Payment, TotPmts As Double
   Dim PayType As DueDate
   Dim Fmt As String
   Dim Response As MsgBoxResult
```

```
    Fmt = "###,###,##0.00"   ' Define money format.
    FVal = 0   ' Usually 0 for a loan.
    PVal = CDbl(InputBox("How much do you want to borrow?"))
    APR = CDbl(InputBox("What is the annual percentage rate of your loan?"))
    If APR > 1 Then APR = APR / 100 ' Ensure proper form.
    TotPmts = CDbl(InputBox("How many monthly payments will you make?"))
    Response = MsgBox("Do you make payments at the end of month?", MsgBoxStyle.YesNo)
    If Response = MsgBoxResult.No Then
       PayType = DueDate.BegOfPeriod
    Else
       PayType = DueDate.BegOfPeriod
    End If
    Payment = Pmt(APR / 12, TotPmts, -PVal, FVal, PayType)
    MsgBox("Your payment will be " & Format(Payment, Fmt) & " per month.")
 End Sub
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Financial

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

PPmt Function

Returns a **Double** specifying the principal payment for a given period of an annuity based on periodic, fixed payments and a fixed interest rate.

```
Function PPmt( _
    ByVal Rate As Double, _
   ByVal Per As Double, _
   ByVal NPer As Double, _
   ByVal PV As Double, _
   Optional ByVal FV As Double = 0, _
   Optional ByVal Due As DueDate = DueDate.EndOfPeriod _
) As Double
```

Parameters

Rate
Required. **Double** specifying interest rate per period. For example, if you get a car loan at an annual percentage rate (APR) of 10 percent and make monthly payments, the rate per period is 0.1/12, or 0.0083.

Per
Required. **Double** specifying payment period in the range 1 through *NPer*.

NPer
Required. **Double** specifying total number of payment periods in the annuity. For example, if you make monthly payments on a four-year car loan, your loan has a total of 4 * 12 (or 48) payment periods.

PV
Required. **Double** specifying present value, or value today, of a series of future payments or receipts. For example, when you borrow money to buy a car, the loan amount is the present value to the lender of the monthly car payments you will make.

FV
Optional. **Double** specifying future value or cash balance you want after you've made the final payment. For example, the future value of a loan is $0 because that's its value after the final payment. However, if you want to save $50,000 over 18 years for your child's education, then $50,000 is the future value. If omitted, 0 is assumed.

Due
Optional. Object of type `Microsoft.VisualBasic.DueDate` that specifies when payments are due. This argument must be either `DueDate.EndOfPeriod` if payments are due at the end of the payment period, or `DueDate.BegOfPeriod` if payments are due at the beginning of the period. If omitted, `DueDate.EndOfPeriod` is assumed.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Per* value invalid: must be > 1 and < *NPer* .

Remarks

An annuity is a series of fixed cash payments made over a period of time. An annuity can be a loan (such as a home mortgage) or an investment (such as a monthly savings plan).

The *Rate* and *NPer* arguments must be calculated using payment periods expressed in the same units. For example, if *Rate* is calculated using months, *NPer* must also be calculated using months.

For all arguments, cash paid out (such as deposits to savings) is represented by negative numbers; cash received (such as dividend checks) is represented by positive numbers.

Example

This example uses the **PPmt** function to calculate how much of a payment for a specific period is principal when all the payments are of equal value. Given are the interest percentage rate per period (`APR / 12`), the payment period for which the principal portion is desired (`Period`), the total number of payments (`TotPmts`), the present value or principal of the loan (`PVal`), the future value of the loan (`FVal`), and a number that indicates whether the payment is due at the beginning or end of the payment period (`PayType`).

```
Sub TestPPMT()
   Dim PVal, APR, TotPmts, MakeChart, FVal, Payment, Period, P, I As Double
   Dim PayType As DueDate
   Dim Msg, Fmt As String
   Dim Response As MsgBoxResult

   Fmt = "###,###,##0.00"   ' Define money format.
   FVal = 0   ' Usually 0 for a loan.
   PVal = CDbl(InputBox("How much do you want to borrow?"))
   APR = CDbl(InputBox("What is the annual percentage rate of your loan?"))
   If APR > 1 Then APR = APR / 100 ' Ensure proper form.
   TotPmts = CDbl(InputBox("How many monthly payments do you have to make?"))
   Response = MsgBox("Do you make payments at the end of month?", MsgBoxStyle.YesNo)
   If Response = MsgBoxResult.No Then
      PayType = DueDate.BegOfPeriod
   Else
      PayType = DueDate.EndOfPeriod
   End If
   Payment = Math.Abs(-Pmt(APR / 12, TotPmts, PVal, FVal, PayType))
   Msg = "Your monthly payment is " & Format(Payment, Fmt) & ". "
   Msg = Msg & "Would you like a breakdown of your principal and "
   Msg = Msg & "interest per period?"
   Response = MsgBox(Msg, MsgBoxStyle.YesNo)   ' See if chart is desired.
   If Response <> MsgBoxResult.No Then
      If TotPmts > 12 Then MsgBox("Only first year will be shown.")
      Msg = "Month  Payment  Principal  Interest" & vbNewLine
      For Period = 1 To TotPmts
         If Period > 12 Then Exit For ' Show only first 12.
         P = PPmt(APR / 12, Period, TotPmts, -PVal, FVal, PayType)
         P = (Int((P + 0.005) * 100) / 100)  ' Round principal.
         I = Payment - P
         I = (Int((I + 0.005) * 100) / 100)  ' Round interest.
         Msg = Msg & Period & vbTab & Format(Payment, Fmt)
         Msg = Msg & vbTab & Format(P, Fmt) & vbTab & Format(I, Fmt) & vbNewLine
      Next Period
      MsgBox(Msg)    ' Display amortization table.
   End If
End Sub
```

Print, PrintLine Functions

Writes display-formatted data to a sequential file.

```
Public Sub Print( _
   ByVal FileNumber As Integer, _
   ByVal ParamArray Output() As Object _
)
```

-or-

```
Public Sub PrintLine( _
   ByVal FileNumber As Integer, _
   ByVal ParamArray Output() As Object _
)
```

Parameters

FileNumber
Required. Any valid file number.
Output
Optional. Zero or more comma-delimited expressions to write to a file.

Output argument settings

The *Output* argument settings are:

Setting	Description
SPC(*n*)	Used to insert space characters in the output, where *n* is the number of space characters to insert.
TAB(*n*)	Used to position the insertion point to an absolute column number, where *n* is the column number. Use **TAB** with no argument to position the insertion point at the beginning of the next print zone.
expression	Numeric expressions or string expressions to print.

Exceptions/Errors

Exception type	Error number	Condition
IOException	54	File mode is invalid.
IOException	52	*FileNumber* does not exist.

Remarks

Print will not include a linefeed at the end of a line; **PrintLine,** however, will include a linefeed.

Data written with **Print** is usually read from a file with **LineInput** or **Input**.

If you omit *Output* for **PrintLine**, a blank line is printed to the file; for **Print,** nothing is output. Multiple expressions separated with a comma will be aligned on tab boundaries, but mixing commas and **TAB** may result in inconsistent results.

For **Boolean** data, either `True` or `False` is printed. The **True** and **False** keywords are not translated, regardless of the locale.

Date data is written to the file using the standard short date format recognized by your system. When either the date or the time component is missing or zero, only the part provided is written to the file.

Nothing is written to the file if *Output* data is empty. However, if *Output* list data is **DBNull**, `Null` is written to the file.

For **Error** data, the output appears as `Error errorcode`. The **Error** keyword is not translated regardless of the locale.

All data written to the file using **Print** is internationally aware; that is, the data is properly formatted using the appropriate decimal separator. If the user wishes to output data for use by multiple locales, then **Write** should be used.

Writing to a file with the **Print** or **PrintLine** functions requires **Write** access from the **FileIOPermissionAccess** enumeration. For more information, see FileIOPermissionAccess Enumeration.

Example

This example uses the **Print** and **PrintLine** functions to write data to a file.

```
FileOpen(1, "c:\trash.txt", OpenMode.Output)   ' Open file for output.
Print(1, "This is a test.")   ' Print text to file.
PrintLine(1)   ' Print blank line to file.
PrintLine(1, "Zone 1", TAB(), "Zone 2")   ' Print in two print zones.
PrintLine(1, "Hello", "World")   ' Separate strings with a tab.
PrintLine(1, SPC(5), "5 leading spaces ")   ' Print five leading spaces.
PrintLine(1, TAB(10), "Hello")   ' Print word at column 10.

' Assign Boolean, Date, and Error values.
Dim aBool As Boolean
Dim aDate As DateTime
aBool = False
aDate = DateTime.Parse("February 12, 1969")

' Dates and booleans are translated using locale settings of your system.
PrintLine(1, aBool, " is a Boolean value")
PrintLine(1, aDate, " is a date")
FileClose(1)   ' Close file.
```

Smart Device Developer Notes

This function is not supported.

Requirements

PV Function

Returns a **Double** specifying the present value of an annuity based on periodic, fixed payments to be paid in the future and a fixed interest rate.

```
Function PV( _
   ByVal Rate As Double, _
   ByVal NPer As Double, _
   ByVal Pmt As Double, _
   Optional ByVal FV As Double = 0, _
   Optional ByVal Due As DueDate = DueDate.EndOfPeriod _
) As Double
```

Parameters

Rate
Required. **Double** specifying interest rate per period. For example, if you get a car loan at an annual percentage rate (APR) of 10 percent and make monthly payments, the rate per period is 0.1/12, or 0.0083.

NPer
Required. **Double** specifying total number of payment periods in the annuity. For example, if you make monthly payments on a four-year car loan, your loan has a total of 4 * 12 (or 48) payment periods.

Pmt
Required. **Double** specifying payment to be made each period. Payments usually contain principal and interest that doesn't change over the life of the annuity.

FV
Optional. **Double** specifying future value or cash balance you want after you've made the final payment. For example, the future value of a loan is $0 because that's its value after the final payment. However, if you want to save $50,000 over 18 years for your child's education, then $50,000 is the future value. If omitted, 0 is assumed.

Due
Optional. Object of type `Microsoft.VisualBasic.DueDate` that specifies when payments are due. This argument must be either `DueDate.EndOfPeriod` if payments are due at the end of the payment period, or `DueDate.BegOfPeriod` if payments are due at the beginning of the period. If omitted, `DueDate.EndOfPeriod` is assumed.

Remarks

An annuity is a series of fixed cash payments made over a period of time. An annuity can be a loan (such as a home mortgage) or an investment (such as a monthly savings plan).

The *Rate* and *NPer* arguments must be calculated using payment periods expressed in the same units. For example, if *Rate* is calculated using months, *NPer* must also be calculated using months.

For all arguments, cash paid out (such as deposits to savings) is represented by negative numbers; cash received (such as dividend checks) is represented by positive numbers.

Example

In this example, the **PV** function returns the present value of an $1,000,000 annuity that will provide $50,000 a year for the next 20 years. Provided are the expected annual percentage rate (`APR`), the total number of payments (`TotPmts`), the amount of each payment (`YrIncome`), the total future value of the investment (`FVal`), and a number that indicates whether each payment is made at the beginning or end of the payment period (`PayType`). Note that `YrIncome` is a negative number because it represents cash paid out from the annuity each year.

```
Sub TestPV()
   Dim Fmt As String = "###,##0.00"    ' Define money format.
   Dim APR, TotPmts, YrIncome, FVal, PVal As Double
   Dim PayType As DueDate
   APR = 0.0825  ' Annual percentage rate.
   TotPmts = 20   ' Total number of payments.
   YrIncome = 50000   ' Yearly income.
   FVal = 1000000   ' Future value.
   PayType = DueDate.BegOfPeriod   ' Payment at beginning of month.
   PVal = PV(APR, TotPmts, -YrIncome, FVal, PayType)
```

```
    MsgBox("The present value is " & Format(PVal, Fmt) & ".")
End Sub
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Financial

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

QBColor Function

Returns an **Integer** value representing the RGB color code corresponding to the specified color number.

```
QBColor(Color)
```

Parameter

Color
Required. A whole number in the range 0–15.

Settings

The *color* argument has these settings:

Number	Color	Number	Color
0	Black	8	Gray
1	Blue	9	Light blue
2	Green	10	Light green
3	Cyan	11	Light cyan
4	Red	12	Light red
5	Magenta	13	Light magenta
6	Yellow	14	Light yellow
7	White	15	Bright white

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Color* is outside of range 0 to 15, inclusive.

Remarks

Starting with the least-significant byte, the returned value specifies the red, green, and blue values used to set the appropriate color in the RGB system used by the Visual Basic language.

Example

This example uses the **QBColor** function to change to the color indicated by `colorInteger`. **QBColor** accepts integer values between 0 and 15.

```
Dim colorInteger As Integer
' Use 4 for red.
colorInteger = QBColor(4)
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Information

Assembly: Microsoft Visual Basic .NET Runtime (in MicrosoftVisualBasic.dll)

See Also

RGB Function | ArgumentException Class

Rate Function

Returns a **Double** specifying the interest rate per period for an annuity.

```
Function Rate( _
   ByVal NPer As Double, _
   ByVal Pmt As Double, _
   ByVal PV As Double, _
   Optional ByVal FV As Double = 0, _
   Optional ByVal Due As DueDate = DueDate.EndOfPeriod, _
   Optional ByVal Guess As Double = 0.1 _
) As Double
```

Parameters

NPer
Required. **Double** specifying total number of payment periods in the annuity. For example, if you make monthly payments on a four-year car loan, your loan has a total of 4 * 12 (or 48) payment periods.

Pmt
Required. **Double** specifying payment to be made each period. Payments usually contain principal and interest that doesn't change over the life of the annuity.

PV
Required. **Double** specifying present value, or value today, of a series of future payments or receipts. For example, when you borrow money to buy a car, the loan amount is the present value to the lender of the monthly car payments you will make.

FV
Optional. **Double** specifying future value or cash balance you want after you make the final payment. For example, the future value of a loan is $0 because that's its value after the final payment. However, if you want to save $50,000 over 18 years for your child's education, then $50,000 is the future value. If omitted, 0 is assumed.

Due
Optional. Object of type `Microsoft.VisualBasic.DueDate` that specifies when payments are due. This argument must be either `DueDate.EndOfPeriod` if payments are due at the end of the payment period, or `DueDate.BegOfPeriod` if payments are due at the beginning of the period. If omitted, `DueDate.EndOfPeriod` is assumed.

Guess
Optional. **Double** specifying value you estimate will be returned by **Rate**. If omitted, *Guess* is 0.1 (10 percent).

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*NPer* <= 0.

Remarks

An annuity is a series of fixed cash payments made over a period of time. An annuity can be a loan (such as a home mortgage) or an investment (such as a monthly savings plan).

For all arguments, cash paid out (such as deposits to savings) is represented by negative numbers; cash received (such as dividend checks) is represented by positive numbers.

Rate is calculated by iteration. Starting with the value of *Guess*, **Rate** cycles through the calculation until the result is accurate to within 0.00001 percent. If **Rate** can't find a result after 20 tries, it fails. If your guess is 10 percent and **Rate** fails, try a different value for *Guess*.

Example

This example uses the **Rate** function to calculate the interest rate of a loan given the total number of payments (`TotPmts`), the amount of the loan payment (`Payment`), the present value or principal of the loan (`PVal`), the future value of the loan (`FVal`), a number that indicates whether the payment is due at the beginning or end of the payment period (`PayType`), and an approximation of the expected interest rate (`Guess`).

```
Sub TestRate()
   Dim PVal, Payment, TotPmts, FVal, Guess, APR As Double
```

```
    Dim PayType As DueDate
    Dim Fmt As String = "##0.00"   ' Define percentage format.
    Dim Response As MsgBoxResult
    FVal = 0   ' Usually 0 for a loan.
    Guess = 0.1  ' Guess of 10 percent.
    PVal = CDbl(InputBox("How much did you borrow?"))
    Payment = CDbl(InputBox("What's your monthly payment?"))
    TotPmts = CDbl(InputBox("How many monthly payments do you have to make?"))
    Response = MsgBox("Do you make payments at the end of the month?", MsgBoxStyle.YesNo)
    If Response = MsgBoxResult.No Then
       PayType = DueDate.BegOfPeriod
    Else
       PayType = DueDate.EndOfPeriod
    End If
    APR = (Rate(TotPmts, -Payment, PVal, FVal, PayType, Guess) * 12) * 100
    MsgBox("Your interest rate is " & Format(CInt(APR), Fmt) & " percent.")
 End Sub
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Financial

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Rename Function

Renames a disk file, directory, or folder.

```
Public Sub Rename( _
   ByVal OldPath As String, _
   ByVal NewPath As String _
)
```

Parameters

OldPath
Required. **String** expression that specifies the existing file name and location. *OldPath* may include the directory or folder, and drive, of the file.

NewPath
Required. **String** expression that specifies the new file name and location. *NewPath* may include directory or folder, and drive of the destination location. The file name specified by *NewPath* can't already exist.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	Pathname is invalid .
FileNotFoundException	53	*OldPath* file does not exist.
IOException	58	*NewPath* file already exists.
IOException	75	Access is invalid.
IOException	74	Cannot rename to different device .

Remarks

The **Rename** function renames a file and moves it to a different directory or folder, if necessary. The **Rename** function can move a file across drives, but it can only rename an existing directory or folder when both *NewPath* and *OldPath* are located on the same drive. Name cannot create a new file, directory, or folder.

Using the **Rename** function on an open file produces an error. You must close an open file before renaming it. **Rename** arguments cannot include multiple-character (*) and single-character (?) wildcards.

Example

This example uses the **Rename** function to rename a file. For purposes of this example, assume that the directories or folders that are specified already exist.

```
Dim OldName, NewName As String
OldName = "OLDFILE"
NewName = "NEWFILE" ' Define file names.
Rename(OldName, NewName)   ' Rename file.

OldName = "C:\MYDIR\OLDFILE"
NewName = "C:\YOURDIR\NEWFILE"
Rename(OldName, NewName)   ' Move and rename file.
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in MicrosoftVisualBasic.dll)

Replace Function

Returns a string in which a specified substring has been replaced with another substring a specified number of times.

```
Public Function Replace(
   ByVal Expression As String,
   ByVal Find As String,
   ByVal Replacement As String,
   Optional ByVal Start As Integer = 1,
   Optional ByVal Count As Integer = -1,
   Optional ByVal Compare As CompareMethod = CompareMethod.Binary
) As String
```

Parameters

Expression
Required. String expression containing substring to replace.
Find
Required. Substring being searched for.
Replacement
Required. Replacement substring.
Start
Optional. Position within *Expression* where substring search is to begin. If omitted, 1 is assumed.
Count
Optional. Number of substring substitutions to perform. If omitted, the default value is –1, which means make all possible substitutions.
Compare
Optional. Numeric value indicating the kind of comparison to use when evaluating substrings. See Settings for values.

Settings

The *Compare* argument can have the following values:

Constant	Description
Binary	Performs a binary comparison
Text	Performs a textual compariso n

Return Values

Replace returns the following values:

If	Replace returns
Expression is zero-length	Zero-length string ("")
Find is zero-length	Copy of *Expression*
Replace is zero-length	Copy of *Expression* with no occurrences of *Find*
Start is greater than length of *expression*	Zero-length string
Count is 0	Copy of *Expression*

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Count* < -1 or *Start* <= 0 .

Remarks

The return value of the **Replace** function is a string that begins at the position specified by *Start* and concludes at the end of the *Expression* string, with the substitutions made as specified by the *Find* and *Replace* values.

Example

This example demonstrates the **Replace** function.

```
Dim myString As String = "Shopping List"
Dim aString As String
' Returns "Shipping List".
aString = Replace(myString, "o", "i")
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Filter Function

Reset Function

Closes all disk files opened using the **FileOpen** function.

```
Public Sub Reset()
```

Remarks

The **Reset** function closes all active files opened by the **FileOpen** function and has the same function as **FileClose()** without any parameters.

Example

This example uses the **Reset** function to close all open files and write the contents of all file buffers to disk. Note the use of the **Object** variable `FileNumber` as both a string and a number.

```
' Open 5 files named TEST1, TEST2, etc.
Dim fileNumber As Integer
For fileNumber = 1 To 5    ' Open 5 files.
   FileOpen(fileNumber, "TEST" & fileNumber, OpenMode.Output)
   PrintLine(fileNumber, "Hello World")
Next fileNumber
Reset()   ' Close files and write contents to disk.
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

FileClose Function | End Statement | FileOpen Function | File Access with Visual Basic Run-Time Functions

RGB Function

Returns an **Integer** value representing an RGB color value from a set of red, green and blue color components.

```
RGB( _
   Red As Integer, _
   Green As Integer, _
   Blue As Integer _
)
```

Parameters

Red
Required. **Integer** in the range 0–255, inclusive, that represents the intensity of the red component of the color.
Green
Required. **Integer** in the range 0–255, inclusive, that represents the intensity of the green component of the color.
Blue
Required. **Integer** in the range 0–255, inclusive, that represents the intensity of the blue component of the color.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Green*, *Blue*, or *Red* outside of range 0 and 255, inclusive.

Remarks

Application methods and properties that accept a color specification expect that specification to be a number representing an RGB color value. An RGB color value specifies the relative intensity of red, green, and blue to cause a specific color to be displayed.

If the value for any argument to **RGB** is greater than 255, 255 is used.

The following table lists some standard colors and the red, green, and blue values they include:

Color	Red value	Green value	Blue value
Black	0	0	0
Blue	0	0	255
Green	0	255	0
Cyan	0	255	255
Red	255	0	0
Magenta	255	0	255
Yellow	255	255	0
White	255	255	255

Example

This example shows how the **RGB** function is used to return a whole number representing an **RGB** color value.

```
Dim red, rgbValue As Integer
Dim i As Integer = 75
red = RGB(255, 0, 0)   ' Return the value for red.
rgbValue = RGB(i, 64 + i, 128 + i)    ' Same as RGB(75, 139, 203).
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Information

Assembly: Microsoft Visual Basic .NET Runtime (in MicrosoftVisualBasic.dll)

See Also

QBColor Function | ArgumentException Class

Right Function

Returns a string containing a specified number of characters from the right side of a string.

```
Public Shared Function Right( _
   ByVal Str As String, _
   ByVal Length As Integer _
) As String
```

Parameters

Str
Required. **String** expression from which the rightmost characters are returned.

Length
Required. **Integer**. Numeric expression indicating how many characters to return. If 0, a zero-length string ("") is returned. If greater than or equal to the number of characters in *Str*, the entire string is returned.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Length* < 0.

Remarks

To determine the number of characters in *Str*, use the **Len** function. If used in a Windows Form, or any other class that has a **Right** property, you must fully qualify the function with `Microsoft.VisualBasic.Right`.

> **Note** The **RightB** function in earlier versions of Visual Basic returns a string in bytes, rather than characters. It is used primarily for converting strings in double-byte character set (DBCS) applications. All Visual Basic .NET strings are in Unicode, and **RightB** is no longer supported.

Example

This example demonstrates the use of the **Right** function to return a substring of a given **String**. In a class that has a **Right** property, it may be necessary to fully qualify the **Right** function.

```
Dim myString As String = "Hello World!"
Dim subString As String
subString = Microsoft.VisualBasic.Right(myString, 6)   ' Returns "World!"
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Left Function | Len Function | Mid Function | ArgumentException Class | Programming Element Support Changes Summary

RmDir Function

Removes an existing directory or folder.

```
Public Sub RmDir(ByVal Path As String)
```

Parameter

Path
Required. **String** expression that identifies the directory or folder to be removed. *Path* may include the drive. If no drive is specified, **RmDir** removes the directory or folder on the current drive.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	52	*Path* is not specified or is empty .
IOException	75	Target directory contains files.
FileNotFoundException	76	Directory does not exist.

Remarks

An error occurs if you try to use **RmDir** on a directory or folder containing files. Use the **Kill** function to delete all files before attempting to remove a directory or folder.

Example

This example uses the **RmDir** function to remove an existing directory or folder.

```
' Assume that MYDIR is an empty directory or folder.
RmDir ("MYDIR")   ' Remove MYDIR.
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in MicrosoftVisualBasic.dll)

See Also

ChDir Function | CurDir Function | Kill Function | MkDir Function | ArgumentException Class | IOException Class | FileNotFoundException Class

Rnd Function

Returns a random number of type **Single**.

```
Public Shared Function Rnd[(number)] As Single
```

Parameter

number
Optional. A **Single** value or any valid **Single** expression.

Return Values

If *number* is	Rnd generates
Less than zero	The same number every time, using *number* as the seed.
Greater than zero	The next random number in the sequence.
Equal to zero	The most recently generated number.
Not supplied	The next random number in the sequence.

Remarks

The **Rnd** function returns a value less than 1, but greater than or equal to zero.

The value of *number* determines how **Rnd** generates a random number:

For any given initial seed, the same number sequence is generated because each successive call to the **Rnd** function uses the previously generated number as a seed for the next number in the sequence.

Before calling **Rnd,** use the **Randomize** statement without an argument to initialize the random-number generator with a seed based on the system timer.

To produce random integers in a given range, use this formula:

```
CInt(Int((upperbound - lowerbound + 1) * Rnd() + lowerbound))
```

Here, *upperbound* is the highest number in the range, and *lowerbound* is the lowest number in the range.

> **Note** To repeat sequences of random numbers, call **Rnd** with a negative argument immediately before using **Randomize** with a numeric argument. Using **Randomize** with the same value for *number* does not repeat the previous sequence.
>
> **Security Note** Because the **Random** statement and the **Rnd** function start with a seed value and generate numbers that fall within a finite range, the results may be predictable by someone who knows the algorithm used to generate them. Consequently, the **Random** statement and the **Rnd** function should not be used to generate random numbers for use in cryptography.

Example

This example uses the **Rnd** function to generate a random integer value from 1 to 6.

```
Dim MyValue As Integer
MyValue = CInt(Int((6 * Rnd()) + 1)) ' Generate random value between 1 and 6.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: VBMath

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Math Summary | Randomize Statement

Math Functions

The math functions in Visual Basic 6 have been replaced by equivalent methods in the **System.Math** class of the .NET Framework.

Remarks

The .NET Framework math methods are functionally identical to their Visual Basic 6 counterparts, although some have slightly different names. For example, the .NET Framework equivalent of the Visual Basic 6 Atn function is **Atan**. The following table lists the Visual Basic 6 math function names and the equivalent .NET Framework methods.

Visual Basic 6 function	Visual Basic .NET method	Description
Abs	Math.Abs Method	Returns the absolute value of a specified number.
Atn	Math.Atan Method	Returns a **Double** value containing the angle whose tangent is the specified number.
Cos	Math.Cos Method	Returns a **Double** value containing the cosine of the specified angle.
Exp	Math.Exp Method	Returns a **Double** value containing e (the base of natural logarithms) raised to the specified power.
Log	Math.Log Method	Returns a **Double** value containing the logarithm of a specified number. This method is overloaded and can return either the natural (base e) logarithm of a specified number or the logarithm of a specified number in a specified base.
Round	Math.Round Method	Returns a **Double** value containing the number nearest the specified value. Additional round functions are available as methods of the intrinsic types such as Decimal.Round Method.
Sgn	Math.Sign Method	Returns an **Integer** value indicating the sign of a number.
Sin	Math.Sin Method	Returns a **Double** value specifying the sine of an angle.
Sqr	Math.Sqrt Method	Returns a **Double** value specifying the square root of a number.
Tan	Math.Tan Method	Returns a **Double** value containing the tangent of an angle.

In addition, the .NET Framework math class provides constants and other static methods for trigonometric, logarithmic, and other common mathematical functions. All of these can be used in a Visual Basic program.

To use these functions without qualification, import the **System.Math** namespace into your project by adding the following code to the top of the source code:

```
Imports System.Math
```

Requirements

Class: Math Class

Abs Example

This example uses the **Abs** method of the **Math** class to compute the absolute value of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyNumber As Double
```

```
MyNumber = Abs(50.3)    ' Returns 50.3.
MyNumber = Abs(-50.3)   ' Returns 50.3.
```

Atan Example

This example uses the **Atan** method of the **Math** class to calculate the value of pi.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim pi As Double
pi = 4 * Atan(1)   ' Calculate the value of pi.
```

Cos Example

This example uses the **Cos** method of the **Math** class to return the cosine of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MySecant As Double
MyAngle = 1.3   ' Define angle in radians.
MySecant = 1 / Cos(MyAngle)   ' Calculate secant.
```

Exp Example

This example uses the **Exp** method of the **Math** class to return *e* raised to a power.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyHSin As Double
' Define angle in radians.
MyAngle = 1.3
' Calculate hyperbolic sine.
MyHSin = (Exp(MyAngle) - Exp(-1 * MyAngle)) / 2
```

Log Example

This example uses the **Log** method of the **Math** class to return the natural logarithm of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyLog As Double
' Define angle in radians.
MyAngle = 1.3
' Calculate inverse hyperbolic sine.
MyLog = Log(MyAngle + Sqrt(MyAngle * MyAngle + 1))
```

Round Example

This example uses the **Round** method of the **Math** class to round a number to the nearest integer.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyVar1 As Double = 2.8
Dim MyVar2 As Double
MyVar2 =Round(MyVar1)   ' Returns 3.
```

Sign Example

This example uses the **Sign** method of the **Math** class to determine the sign of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyVar1, MyVar2, MyVar3 As Double
Dim MySign As Integer
MyVar1 = 12
MyVar2 = -2.4
MyVar3 = 0
MySign = Sign(MyVar1)   ' Returns 1.
MySign = Sign(MyVar2)   ' Returns -1.
MySign = Sign(MyVar3)   ' Returns 0.
```

Sin Example

This example uses the **Sin** method of the **Math** class to return the sine of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyCosecant As Double
MyAngle = 1.3   ' Define angle in radians.
MyCosecant = 1 / Sin(MyAngle)   ' Calculate cosecant.
```

Sqrt Example

This example uses the **Sqrt** method of the **Math** class to calculate the square root of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MySqr As Double
MySqr = Sqrt(4)    ' Returns 2.
MySqr = Sqrt(23)   ' Returns 4.79583152331272.
MySqr = Sqrt(0)    ' Returns 0.
MySqr = Sqrt(-4)   ' Returns NaN (not a number).
```

Tan Example

This example uses the **Tan** method of the **Math** class to return the tangent of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyCotangent As Double
MyAngle = 1.3   ' Define angle in radians.
MyCotangent = 1 / Tan(MyAngle)   ' Calculate cotangent.
```

Requirements

Namespace: System.Math

Assembly: mscorlib (in mscorlib.dll)

See Also

Rnd Function | Randomize Statement | Derived Math Functions | Double.NaN Field

RSet Function

Returns a right-aligned string containing the specified string adjusted to the specified length.

```
Public Shared Function RSet( _
   ByVal Source As String, _
   ByVal Length As Integer _
) As String
```

Parameters

Source
Required. **String** expression. Name of string variable.
Length
Required. **Integer** expression. Length of returned string.

Remarks

If *Source* is longer than *Length*, **RSet** places only the leftmost characters, up to the length of *Source,* in the returned string. If the specified string is shorter than the specified length, spaces are added to the left end of the string to produce the appropriate length. If the specified string is longer than the specified length, it is shortened to the specified length.

Example

This example demonstrates the use of the **RSet** function.

```
Dim myString As String = "Right"
Dim rString As String
rString = RSet(myString, 11)   ' Returns "      Right"
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Data Type Summary | LSet Function | Efficient Use of Data Types

LTrim, RTrim, and Trim Functions

Returns a string containing a copy of a specified string with no leading spaces (**LTrim**), no trailing spaces (**RTrim**), or no leading or trailing spaces (**Trim**).

```
Public Shared Function LTrim(ByVal Str As String) As String
Public Shared Function RTrim(ByVal Str As String) As String
Public Shared Function Trim(ByVal Str As String) As String
```

Parameter

Str
Required. Any valid **String** expression.

Example

This example uses the **LTrim** function to strip leading spaces and the **RTrim** function to strip trailing spaces from a string variable. It uses the **Trim** function to strip both types of spaces.

```
Dim MyString, TrimString As String
MyString = "  <-Trim->  "   ' Initializes string.
TrimString = LTrim(MyString)   ' TrimString = "<-Trim->  ".
TrimString = RTrim(MyString)   ' TrimString = "  <-Trim->".
TrimString = LTrim(RTrim(MyString))   ' TrimString = "<-Trim->".
' Using the Trim function alone achieves the same result.
TrimString = Trim(MyString)   ' TrimString = "<-Trim->".
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Left Function | Right Function

S-Z Functions

The following table contains a listing of the Visual Basic .NET run-time member functions.

SaveSetting	Second	Seek	SetAttr
Sgn	Shell	Sin	SLN
Space	SPC	Split	Sqr
Str	StrComp	StrConv	StrDup
StrReverse	Switch	SYD	SystemTypeName
TAB	Tan	TimeSerial	TimeValue
Trim	TypeName	UBound	UCase
Unlock	Val	VarType	VbTypeName
Weekday	WeekdayName	Write	WriteLine
Year			

See Also

A-C Functions | D-G Functions | H-L Functions | M-R Functions | Visual Basic Language and Run-Time Reference

SaveSetting Function

Saves or creates an application entry in the Windows registry.

```
Public Sub SaveSetting( _
   ByVal AppName As String, _
   ByVal Section As String, _
   ByVal Key As String, _
   ByVal Setting As String _
)
```

Parameters

AppName
Required. **String** expression containing the name of the application or project to which the setting applies.
Section
Required. **String** expression containing the name of the section in which the key setting is being saved.
Key
Required. **String** expression containing the name of the key setting being saved.
Setting
Required. Expression containing the value to which *Key* is being set.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	Key registry could not be created, or user is not logged in.

Remarks

The **SaveSetting** function adds the key to HKEY_CURRENT_USER\Software\VB and VBA Program Settings.

If the key setting can't be saved for any reason, an error occurs.

SaveSetting requires that a user be logged on since it operates under the HKEY_LOCAL_USER registry key, which is not active until a user logs on interactively.

Registry settings that are to be accessed from a non-interactive process (such as mtx.exe) should be stored under either the HKEY_LOCAL_MACHINE\Software\ or the HKEY_USER\DEFAULT\Software registry keys.

GetSetting requires **Write** and **Create** Registry Permission.

Example

The following example first uses the **SaveSetting** function to make entries in the Windows registry for the `MyApp` application, and then uses the **DeleteSetting** function to remove them.

```
' Place some settings in the registry.
SaveSetting("MyApp", "Startup", "Top", "75")
SaveSetting("MyApp","Startup", "Left", "50")
' Remove Startup section and all its settings from registry.
DeleteSetting ("MyApp", "Startup")
' Remove MyApp from the registry.
DeleteSetting ("MyApp")
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: Interaction

Assembly: Microsoft.Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

DeleteSetting Function | GetAllSettings Function | GetSetting Function | RegistryPermission Class

Second Function

Returns an **Integer** value from 0 through 59 representing the second of the minute.

```
Public Function Second(ByVal TimeValue As DateTime) As Integer
```

Parameter

TimeValue
Required. **Date** value from which you want to extract the second.

You can also obtain the second of the minute by calling **DatePart** and specifying **DateInterval.Second** for the *Interval* argument.

Example

This example uses the **Second** function to obtain the second of the minute from a specified time. In the development environment, the time literal is displayed in short time format using the locale settings of your code.

```
Dim MyTime As Date
Dim MySecond As Integer
MyTime = #4:35:17 PM#   ' Assign a time.
MySecond = Second(MyTime)   ' MySecond contains 17.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: DateAndTime

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Day Function | Hour Function | Minute Function | Now Property | TimeOfDay Property | DatePart Function | System Namespace | DateTime Structure | ArgumentException Class | ArgumentOutOfRangeException Class

Seek Function

Returns a **Long** specifying the current read/write position within a file opened using the **FileOpen** function or sets the position for the next read/write operation within a file opened using the **FileOpen** function.

```
Public Overloads Function Seek( _
   ByVal FileNumber As Integer _
) As Long
```

-or-

```
Public Overloads Sub Seek( _
   ByVal FileNumber As Integer, _
   ByVal Position As Long _
)
```

Parameter

FileNumber
Required. An **Integer** containing a valid file number.
Position
Required. Number in the range 1 – 2,147,483,647, inclusive, that indicates where the next read/write operation should occur.

Exceptions/Errors

Exception type	Error number	Condition
IOException	52	*FileNumber* does not exist.
IOException	54	File mode is invalid.

Remarks

Seek returns a value between 1 and 2,147,483,647 (equivalent to 2^31 – 1), inclusive.

The following describes the return values for each file access mode:

Mode	Return Value
Random	Number of the next record read or written
Binary, **Input, Output**, **Append**	Byte position at which the next operation takes place. The first byte in a file is at position 1, the seco nd byte is at position 2, and so on.

Example

This example uses the **Seek** function to return the current file position. The example assumes `TESTFILE` is a file containing records of the structure `Record`.

```
Structure Record   ' Define user-defined type.
   ID As Integer
   Name As String
End Structure
```

For files opened in **Random** mode, **Seek** returns the number of next record.

```
Dim MyRecord As Record
FileOpen(1, "TESTFILE", OpenMode.Random)
Do While Not EOF(1)
   Debug.WriteLine(Seek(1))   ' Print record number.
   FileGet(1, MyRecord)   ' Read next record.
Loop
FileClose(1)
```

For files opened in modes other than **Random** mode, **Seek** returns the byte position at which the next operation takes place. Assume `TESTFILE` is a file containing a few lines of text.

```
' Print character position at beginning of each line.
Dim TextLine As String
FileOpen(1, "TESTFILE", OpenMode.Input)   ' Open file for reading.
While Not EOF(1)
   TextLine = LineInput(1)   ' Read next line.
   Debug.WriteLine(Seek(1))   ' Position of next line.
End While
FileClose(1)
```

This example uses the **Seek** function to set the position for the next read or write within a file. This example assumes `people.txt` is a file containing records of the structure `Record`.

```
Structure Record
   Dim Name As String
   Dim ID As Integer
End Structure
```

For files opened in **Random** mode, **Seek** sets the next record.

```
Public Sub SeekAPerson(ByVal index As Integer)
   Try
      FileOpen(1, "c:\people.txt", OpenMode.Random)
      Dim onePerson As Record
      Seek(1, index)
      FileGet(1, onePerson)
      FileClose(1)
      Console.WriteLine(onePerson.Name & " " & onePerson.ID)
   Catch
      ' Error recovery code here.
   End Try
End Sub
```

For files opened in modes other than **Random** mode, **Seek** sets the byte position at which the next operation takes place. Assume `TESTFILE` is a file containing a few lines of text.

```
Dim someText As String
FileOpen(1, "TESTFILE", OpenMode.Input)   ' Open file for output.
Seek(1, 3)   ' Move to the third character.
Input(1, someText)
Console.WriteLine(someText)
FileClose(1)
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

FileGet Function | Loc Function | FileOpen Function | FilePut Function | IOException Class

SetAttr Function

Sets attribute information for a file.

```
Public Sub SetAttr( _
   ByVal PathName As String, _
   ByVal Attributes As FileAttribute _
)
```

Parameters

PathName
Required. **String** expression that specifies a file name. *PathName* may include directory or folder, and drive.
Attributes
Required. Constant or numeric expression, whose sum specifies file attributes.

Settings

The *Attributes* argument enumeration values are:

Value	Constant	Description
Normal	**vbNormal**	Normal (default).
ReadOnly	**vbReadOnly**	Read-only.
Hidden	**vbHidden**	Hidden.
System	**vbSystem**	System file.
Volume	**vbVolume**	Volume label
Directory	**vbDirectory**	Directory or folder.
Archive	**vbArchive**	File has changed since last backup.
Alias	**vbAlias**	File has a different name.

Note These enumerations are specified by the Visual Basic language. The names can be used anywhere in your code in place of the actual values.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	52	*PathName* invalid or does not exist .
ArgumentException	5	*Attribute* type is invalid.

Remarks

A run-time error occurs if you try to set the attributes of an open file.

Example

This example uses the **SetAttr** function to set attributes for a file.

```
SetAttr("TESTFILE", vbHidden)   ' Set hidden attribute.
SetAttr("TESTFILE", vbHidden Or vbReadOnly)   ' Set hidden and read-only
   ' attributes.
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in MicrosoftVisualBasic.dll)

FileAttr Function | GetAttr Function | ArgumentException Class | FileAttribute Enumeration

Math Functions

The math functions in Visual Basic 6 have been replaced by equivalent methods in the **System.Math** class of the .NET Framework.

Remarks

The .NET Framework math methods are functionally identical to their Visual Basic 6 counterparts, although some have slightly different names. For example, the .NET Framework equivalent of the Visual Basic 6 Atn function is **Atan**. The following table lists the Visual Basic 6 math function names and the equivalent .NET Framework methods.

Visual Basic 6 function	Visual Basic .NET method	Description
Abs	Math.Abs Method	Returns the absolute value of a specified number.
Atn	Math.Atan Method	Returns a **Double** value containing the angle whose tangent is the specified number.
Cos	Math.Cos Method	Returns a **Double** value containing the cosine of the specified angle.
Exp	Math.Exp Method	Returns a **Double** value containing e (the base of natural logarithms) raised to the specified power.
Log	Math.Log Method	Returns a **Double** value containing the logarithm of a specified number. This method is overloaded and can return either the natural (base e) logarithm of a specified number or the logarithm of a specified number in a specified base.
Round	Math.Round Method	Returns a **Double** value containing the number nearest the specified value. Additional round functions are available as methods of the intrinsic types such as Decimal.Round Method.
Sgn	Math.Sign Method	Returns an **Integer** value indicating the sign of a number.
Sin	Math.Sin Method	Returns a **Double** value specifying the sine of an angle.
Sqr	Math.Sqrt Method	Returns a **Double** value specifying the square root of a number.
Tan	Math.Tan Method	Returns a **Double** value containing the tangent of an angle.

In addition, the .NET Framework math class provides constants and other static methods for trigonometric, logarithmic, and other common mathematical functions. All of these can be used in a Visual Basic program.

To use these functions without qualification, import the **System.Math** namespace into your project by adding the following code to the top of the source code:

```
Imports System.Math
```

Requirements

Class: Math Class

Abs Example

This example uses the **Abs** method of the **Math** class to compute the absolute value of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyNumber As Double
```

```
MyNumber = Abs(50.3)    ' Returns 50.3.
MyNumber = Abs(-50.3)   ' Returns 50.3.
```

Atan Example

This example uses the **Atan** method of the **Math** class to calculate the value of pi.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim pi As Double
pi = 4 * Atan(1)   ' Calculate the value of pi.
```

Cos Example

This example uses the **Cos** method of the **Math** class to return the cosine of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MySecant As Double
MyAngle = 1.3   ' Define angle in radians.
MySecant = 1 / Cos(MyAngle)   ' Calculate secant.
```

Exp Example

This example uses the **Exp** method of the **Math** class to return *e* raised to a power.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyHSin As Double
' Define angle in radians.
MyAngle = 1.3
' Calculate hyperbolic sine.
MyHSin = (Exp(MyAngle) - Exp(-1 * MyAngle)) / 2
```

Log Example

This example uses the **Log** method of the **Math** class to return the natural logarithm of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyLog As Double
' Define angle in radians.
MyAngle = 1.3
' Calculate inverse hyperbolic sine.
MyLog = Log(MyAngle + Sqrt(MyAngle * MyAngle + 1))
```

Round Example

This example uses the **Round** method of the **Math** class to round a number to the nearest integer.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyVar1 As Double = 2.8
Dim MyVar2 As Double
MyVar2 =Round(MyVar1)   ' Returns 3.
```

Sign Example

This example uses the **Sign** method of the **Math** class to determine the sign of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyVar1, MyVar2, MyVar3 As Double
Dim MySign As Integer
MyVar1 = 12
MyVar2 = -2.4
MyVar3 = 0
MySign = Sign(MyVar1)   ' Returns 1.
MySign = Sign(MyVar2)   ' Returns -1.
MySign = Sign(MyVar3)   ' Returns 0.
```

Sin Example

This example uses the **Sin** method of the **Math** class to return the sine of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyCosecant As Double
MyAngle = 1.3   ' Define angle in radians.
MyCosecant = 1 / Sin(MyAngle)   ' Calculate cosecant.
```

Sqrt Example

This example uses the **Sqrt** method of the **Math** class to calculate the square root of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MySqr As Double
MySqr = Sqrt(4)    ' Returns 2.
MySqr = Sqrt(23)   ' Returns 4.79583152331272.
MySqr = Sqrt(0)    ' Returns 0.
MySqr = Sqrt(-4)   ' Returns NaN (not a number).
```

Tan Example

This example uses the **Tan** method of the **Math** class to return the tangent of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyCotangent As Double
MyAngle = 1.3   ' Define angle in radians.
MyCotangent = 1 / Tan(MyAngle)   ' Calculate cotangent.
```

Requirements

Namespace: System.Math

Assembly: mscorlib (in mscorlib.dll)

See Also

Rnd Function | Randomize Statement | Derived Math Functions | Double.NaN Field

Shell Function

Runs an executable program and returns an integer containing the program's process ID if it is still running.

```
Public Function Shell( _
   ByVal Pathname As String, _
   Optional ByVal Style As AppWinStyle = AppWinStyle.MinimizedFocus, _
   Optional ByVal Wait As Boolean = False, _
   Optional ByVal Timeout As Integer = -1 _
) As Integer
```

Parameters

Pathname
Required. **String**. Name of the program to execute, together with any required arguments and command-line switches. *Pathname* can also include the drive and the directory path or folder.

Style
Optional. **AppWinStyle**. A value chosen from the **AppWinStyle** enumeration corresponding to the style of the window in which the program is to be run. If *Style* is omitted, **Shell** uses **AppWinStyle.MinimizedFocus**, which starts the program minimized and with focus.

The *Style* argument can have one of the following settings:

Enumeration value	Description
AppWinStyle.Hide	The window is hidden and focus is given to the hidden window.
AppWinStyle.NormalFocus	The window is given focus and displayed in its most recent size and position.
AppWinStyle.MinimizedFocus	The window is given focus and displayed as an icon.
AppWinStyle.MaximizedFocus	The window is given focus and displayed using the entire screen.
AppWinStyle.NormalNoFocus	The window is set to its most recent size and position. The currently active window remains in focus.
AppWinStyle.MinimizedNoFocus	The window is displayed as an icon. The currently active window remains in focus.

Wait
Optional. **Boolean**. A value indicating whether the **Shell** function should wait for completion of the program. If *Wait* is omitted, **Shell** uses **False**.

Timeout
Optional. **Integer**. The number of milliseconds to wait for completion if *Wait* is **True**. If *Timeout* is omitted, **Shell** uses -1, which means there is no timeout and **Shell** does not return until the program completes. Therefore, if you omit *Timeout* or set it to -1, it is possible that **Shell** might never return control to your program.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Style* is not within range 0 through 9, inclusive.
FileNotFoundException	53	**Shell** cannot start the named program.

Remarks

The return value of the **Shell** function depends on whether the program named in *Pathname* is still executing when **Shell** returns. If you set *Wait* to **True** and the program finishes before the timeout expires, **Shell** returns zero. If the timeout expires, or if you omit *Wait* or set it to **False**, **Shell** returns the process ID of the program. The process ID is a unique number that identifies the running program.

If the **Shell** function cannot start the named program, a **System.IO.FileNotFoundException** error occurs. This can happen, for example, when you attempt to run a 16-bit program, such as `command.com`, from an application using **System.Windows.Forms**. For a workaround, you can run a 32-bit program that calls the desired 16-bit program. In the case of `command.com`, you can run `cmd.exe` as an alternative.

By default, the **Shell** function runs the program asynchronously. This means that a program started with the **Shell** function might not finish executing before the statements following the **Shell** function are executed. If you want to wait for the program to finish before you continue, set *Wait* to **True**.

You should always enclose the entire path and file specification in quotes, as the following example shows:

```
ID = Shell("""C:\Program Files\MyFile.exe"" -a -q", , True, 100000)
```

Each pair of adjacent double quotes (`""`) within the string literal is interpreted as one double quote character in the string. Therefore, the preceding example presents the following string to the **Shell** function:

```
"C:\Program Files\MyFile.exe" -a -q
```

If you did not have the path enclosed in quotes, Windows would look for a file called `Program.exe` in the C:\ directory, instead of `MyFile.exe` in the C:\Program Files directory.

> **Security Note** If you do not enclose the path and file specification in quotes, there is a security risk if the file name or a path node contains spaces. In the preceding example, the path node `\Program Files` includes a space. If the specification were not inside quotes and a program named `Program.exe` had been installed in C:\, for example by illicit tampering, Windows would execute it instead of `MyFile.exe`.
>
> **Security Note** The **Shell** function requires unmanaged code permission, which might affect its execution in partial trust situations. For more information, see SecurityPermission Class and Code Access Permissions.

Example

This example uses the **Shell** function to run an application specified by the user. Specifying **AppWinStyle.NormalFocus** as the second argument opens the application in normal size and gives it the focus.

```
Dim ProcID As Integer
   ' Run Calculator.
ProcID = Shell("C:\Windows\system32\calc.exe", AppWinStyle.NormalFocus)
' The preceding path is for Windows XP;
' The Windows 2000 path is C:\WINNT\system32\calc.exe.
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: Interaction

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Math Functions

The math functions in Visual Basic 6 have been replaced by equivalent methods in the **System.Math** class of the .NET Framework.

Remarks

The .NET Framework math methods are functionally identical to their Visual Basic 6 counterparts, although some have slightly different names. For example, the .NET Framework equivalent of the Visual Basic 6 Atn function is **Atan**. The following table lists the Visual Basic 6 math function names and the equivalent .NET Framework methods.

Visual Basic 6 function	Visual Basic .NET method	Description
Abs	Math.Abs Method	Returns the absolute value of a specified number.
Atn	Math.Atan Method	Returns a **Double** value containing the angle whose tangent is the specified number.
Cos	Math.Cos Method	Returns a **Double** value containing the cosine of the specified angle.
Exp	Math.Exp Method	Returns a **Double** value containing e (the base of natural logarithms) raised to the specified power.
Log	Math.Log Method	Returns a **Double** value containing the logarithm of a specified number. This method is overloaded and can return either the natural (base e) logarithm of a specified number or the logarithm of a specified number in a specified base.
Round	Math.Round Method	Returns a **Double** value containing the number nearest the specified value. Additional round functions are available as methods of the intrinsic types such as Decimal.Round Method.
Sgn	Math.Sign Method	Returns an **Integer** value indicating the sign of a number.
Sin	Math.Sin Method	Returns a **Double** value specifying the sine of an angle.
Sqr	Math.Sqrt Method	Returns a **Double** value specifying the square root of a number.
Tan	Math.Tan Method	Returns a **Double** value containing the tangent of an angle.

In addition, the .NET Framework math class provides constants and other static methods for trigonometric, logarithmic, and other common mathematical functions. All of these can be used in a Visual Basic program.

To use these functions without qualification, import the **System.Math** namespace into your project by adding the following code to the top of the source code:

```
Imports System.Math
```

Requirements

Class: Math Class

Abs Example

This example uses the **Abs** method of the **Math** class to compute the absolute value of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyNumber As Double
```

```
MyNumber = Abs(50.3)    ' Returns 50.3.
MyNumber = Abs(-50.3)   ' Returns 50.3.
```

Atan Example

This example uses the **Atan** method of the **Math** class to calculate the value of pi.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim pi As Double
pi = 4 * Atan(1)   ' Calculate the value of pi.
```

Cos Example

This example uses the **Cos** method of the **Math** class to return the cosine of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MySecant As Double
MyAngle = 1.3   ' Define angle in radians.
MySecant = 1 / Cos(MyAngle)   ' Calculate secant.
```

Exp Example

This example uses the **Exp** method of the **Math** class to return *e* raised to a power.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyHSin As Double
' Define angle in radians.
MyAngle = 1.3
' Calculate hyperbolic sine.
MyHSin = (Exp(MyAngle) - Exp(-1 * MyAngle)) / 2
```

Log Example

This example uses the **Log** method of the **Math** class to return the natural logarithm of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyLog As Double
' Define angle in radians.
MyAngle = 1.3
' Calculate inverse hyperbolic sine.
MyLog = Log(MyAngle + Sqrt(MyAngle * MyAngle + 1))
```

Round Example

This example uses the **Round** method of the **Math** class to round a number to the nearest integer.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyVar1 As Double = 2.8
Dim MyVar2 As Double
MyVar2 =Round(MyVar1)   ' Returns 3.
```

Sign Example

This example uses the **Sign** method of the **Math** class to determine the sign of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyVar1, MyVar2, MyVar3 As Double
Dim MySign As Integer
MyVar1 = 12
MyVar2 = -2.4
MyVar3 = 0
MySign = Sign(MyVar1)   ' Returns 1.
MySign = Sign(MyVar2)   ' Returns -1.
MySign = Sign(MyVar3)   ' Returns 0.
```

Sin Example

This example uses the **Sin** method of the **Math** class to return the sine of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyCosecant As Double
MyAngle = 1.3   ' Define angle in radians.
MyCosecant = 1 / Sin(MyAngle)   ' Calculate cosecant.
```

Sqrt Example

This example uses the **Sqrt** method of the **Math** class to calculate the square root of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MySqr As Double
MySqr = Sqrt(4)    ' Returns 2.
MySqr = Sqrt(23)   ' Returns 4.79583152331272.
MySqr = Sqrt(0)    ' Returns 0.
MySqr = Sqrt(-4)   ' Returns NaN (not a number).
```

Tan Example

This example uses the **Tan** method of the **Math** class to return the tangent of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyCotangent As Double
MyAngle = 1.3   ' Define angle in radians.
MyCotangent = 1 / Tan(MyAngle)   ' Calculate cotangent.
```

Requirements

Namespace: System.Math

Assembly: mscorlib (in mscorlib.dll)

See Also

Rnd Function | Randomize Statement | Derived Math Functions | Double.NaN Field

SLN Function

Returns a **Double** specifying the straight-line depreciation of an asset for a single period.

```
Function SLN( _
   ByVal Cost As Double, _
   ByVal Salvage As Double, _
   ByVal Life As Double _
) As Double
```

Parameters

Cost
Required. **Double** specifying initial cost of the asset.
Salvage
Required. **Double** specifying value of the asset at the end of its useful life.
Life
Required. **Double** specifying length of the useful life of the asset.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Life* = 0.

Remarks

The depreciation period must be expressed in the same unit as the *Life* argument. All arguments must be positive numbers.

Example

This example uses the **SLN** function to return the straight-line depreciation of an asset for a single period given the asset's initial cost (`InitCost`), the salvage value at the end of the asset's useful life (`SalvageVal`), and the total life of the asset in years (`LifeTime`).

```
Sub TestSLN()
   Dim InitCost, SalvageVal, MonthLife As Double
   Dim LifeTime, Pdepr As Double
   Dim Fmt As String = "###,##0.00"   ' Define money format.
   Const YEARMONTHS As Integer = 12  ' Number of months in a year.

   InitCost = CDbl(InputBox("What's the initial cost of the asset?"))
   SalvageVal = CDbl(InputBox("What's the asset's value at the end of its useful life?"))
   MonthLife = CDbl(InputBox("What's the asset's useful life in months?"))
   Do While MonthLife < YEARMONTHS   ' Ensure period is >= 1 year.
      MsgBox("Asset life must be a year or more.")
      MonthLife = CDbl(InputBox("What's the asset's useful life in months?"))
   Loop
   LifeTime = MonthLife / YEARMONTHS   ' Convert months to years.
   If LifeTime <> Int(MonthLife / YEARMONTHS) Then
      LifeTime = Int(LifeTime + 1)   ' Round up to nearest year.
   End If
   Pdepr = SLN(InitCost, SalvageVal, LifeTime)
   MsgBox("The depreciation is " & Format(Pdepr, Fmt) & " per year.")
End Sub
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Financial

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

DDB Function | FV Function | IPmt Function | IRR Function | MIRR Function | NPer Function | NPV Function | Pmt Function | PPmt Function | PV Function | Rate Function | SYD Function | ArgumentException Class

Space Function

Returns a string consisting of the specified number of spaces.

```
Public Shared Function Space(ByVal Number As Integer) As String
```

Parameter

Number
Required. **Integer** expression. The number of spaces you want in the string.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Number* < 0.

Remarks

The **Space** function is useful for formatting output and clearing data in fixed-length strings.

Example

This example uses the **Space** function to return a string consisting of a specified number of spaces.

```
Dim MyString As String
' Returns a string with 10 spaces.
MyString = Space(10)
' Inserts 10 spaces between two strings.
MyString = "Hello" & Space(10) & "World"
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

SPC Function | ArgumentException Class

SPC Function

Used with the **Print** or **PrintLine** functions to position output.

```
Public Function SPC(ByVal Count As Short) As SPCInfo
```

Parameters

Count
Required. The number of spaces to insert before displaying or printing the next expression in a list.

Remarks

If *Count* is less than the output line width, the next print position immediately follows the number of spaces printed. If *Count* is greater than the output line width, **SPC** calculates the next print position using the formula:

```
currentprintposition + (Count Mod width)
```

For example, if the current print position is 24, the output line width is 80, and you specify **SPC(**90**)**, the next print will start at position 34 (current print position + the remainder of 90/80). If the difference between the current print position and the output line width is less than *Count* (or *Count* **Mod** *width*), the **SPC** function skips to the beginning of the next line and generates spaces equal to *Count* – (*width* – *currentprintposition*).

Note Make sure your tabular columns are wide enough to accommodate wide letters.

Example

This example uses the **SPC** function to position output in a file and in the **Output** window.

```
' The SPC function can be used with the Print function.
FileOpen(1, "TESTFILE", OpenMode.Output)   ' Open file for output.
Print(1, "10 spaces between here", SPC(10), "and here.")
FileClose(1)   ' Close file.
```

The following statement causes the text to be printed in the **Output** window (using the **WriteLine** method), preceded by 30 spaces.

```
Debug.WriteLine(SPC(30), "Thirty spaces later...")
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Mod Operator | Print, PrintLine Functions | Space Function | TAB Function | FileWidth Function

Split Function

Returns a zero-based, one-dimensional array containing a specified number of substrings.

```
Function Split(
   ByVal Expression As String,
   Optional ByVal Delimiter As String = " ",
   Optional ByVal Limit As Integer = -1,
   Optional ByVal Compare As CompareMethod = CompareMethod.Binary
) As String()
```

Parameters

Expression
Required. **String** expression containing substrings and delimiters. If *Expression* is a zero-length string ("""), *the* **Split** function returns an array of length one, containing an empty string.

Delimiter
Optional. Single character used to identify substring limits. If *Delimiter* is omitted, the space character (" ") is assumed to be the delimiter. If *Delimiter* is a zero-length string, a single-element array containing the entire *Expression* string is returned.

Limit
Optional. Number of substrings to be returned; the default, –1, indicates that all substrings are returned.

Compare
Optional. Numeric value indicating the comparison to use when evaluating substrings. See Settings for values.

Settings

The *Compare* argument can have the following values:

Constant	Description
Binary	Performs a binary comparison
Text	Performs a textual compariso n

Example

The following example demonstrates the **Split** function:

```
Dim myString As String = "Look at these!"
' Returns ["Look", "at", "these!"]
Dim myArray() As String = Split(myString)
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Math Functions

The math functions in Visual Basic 6 have been replaced by equivalent methods in the **System.Math** class of the .NET Framework.

Remarks

The .NET Framework math methods are functionally identical to their Visual Basic 6 counterparts, although some have slightly different names. For example, the .NET Framework equivalent of the Visual Basic 6 Atn function is **Atan**. The following table lists the Visual Basic 6 math function names and the equivalent .NET Framework methods.

Visual Basic 6 function	Visual Basic .NET method	Description
Abs	Math.Abs Method	Returns the absolute value of a specified number.
Atn	Math.Atan Method	Returns a **Double** value containing the angle whose tangent is the specified number.
Cos	Math.Cos Method	Returns a **Double** value containing the cosine of the specified angle.
Exp	Math.Exp Method	Returns a **Double** value containing e (the base of natural logarithms) raised to the specified power.
Log	Math.Log Method	Returns a **Double** value containing the logarithm of a specified number. This method is overloaded and can return either the natural (base e) logarithm of a specified number or the logarithm of a specified number in a specified base.
Round	Math.Round Method	Returns a **Double** value containing the number nearest the specified value. Additional round functions are available as methods of the intrinsic types such as Decimal.Round Method.
Sgn	Math.Sign Method	Returns an **Integer** value indicating the sign of a number.
Sin	Math.Sin Method	Returns a **Double** value specifying the sine of an angle.
Sqr	Math.Sqrt Method	Returns a **Double** value specifying the square root of a number.
Tan	Math.Tan Method	Returns a **Double** value containing the tangent of an angle.

In addition, the .NET Framework math class provides constants and other static methods for trigonometric, logarithmic, and other common mathematical functions. All of these can be used in a Visual Basic program.

To use these functions without qualification, import the **System.Math** namespace into your project by adding the following code to the top of the source code:

```
Imports System.Math
```

Requirements

Class: Math Class

Abs Example

This example uses the **Abs** method of the **Math** class to compute the absolute value of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyNumber As Double
```

```
MyNumber = Abs(50.3)    ' Returns 50.3.
MyNumber = Abs(-50.3)   ' Returns 50.3.
```

Atan Example

This example uses the **Atan** method of the **Math** class to calculate the value of pi.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim pi As Double
pi = 4 * Atan(1)   ' Calculate the value of pi.
```

Cos Example

This example uses the **Cos** method of the **Math** class to return the cosine of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MySecant As Double
MyAngle = 1.3   ' Define angle in radians.
MySecant = 1 / Cos(MyAngle)   ' Calculate secant.
```

Exp Example

This example uses the **Exp** method of the **Math** class to return *e* raised to a power.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyHSin As Double
' Define angle in radians.
MyAngle = 1.3
' Calculate hyperbolic sine.
MyHSin = (Exp(MyAngle) - Exp(-1 * MyAngle)) / 2
```

Log Example

This example uses the **Log** method of the **Math** class to return the natural logarithm of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyLog As Double
' Define angle in radians.
MyAngle = 1.3
' Calculate inverse hyperbolic sine.
MyLog = Log(MyAngle + Sqrt(MyAngle * MyAngle + 1))
```

Round Example

This example uses the **Round** method of the **Math** class to round a number to the nearest integer.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyVar1 As Double = 2.8
Dim MyVar2 As Double
MyVar2 =Round(MyVar1)   ' Returns 3.
```

Sign Example

This example uses the **Sign** method of the **Math** class to determine the sign of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyVar1, MyVar2, MyVar3 As Double
Dim MySign As Integer
MyVar1 = 12
MyVar2 = -2.4
MyVar3 = 0
MySign = Sign(MyVar1)   ' Returns 1.
MySign = Sign(MyVar2)   ' Returns -1.
MySign = Sign(MyVar3)   ' Returns 0.
```

Sin Example

This example uses the **Sin** method of the **Math** class to return the sine of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyCosecant As Double
MyAngle = 1.3   ' Define angle in radians.
MyCosecant = 1 / Sin(MyAngle)   ' Calculate cosecant.
```

Sqrt Example

This example uses the **Sqrt** method of the **Math** class to calculate the square root of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MySqr As Double
MySqr = Sqrt(4)    ' Returns 2.
MySqr = Sqrt(23)   ' Returns 4.79583152331272.
MySqr = Sqrt(0)    ' Returns 0.
MySqr = Sqrt(-4)   ' Returns NaN (not a number).
```

Tan Example

This example uses the **Tan** method of the **Math** class to return the tangent of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyCotangent As Double
MyAngle = 1.3   ' Define angle in radians.
MyCotangent = 1 / Tan(MyAngle)   ' Calculate cotangent.
```

Requirements

Namespace: System.Math

Assembly: mscorlib (in mscorlib.dll)

See Also

Rnd Function | Randomize Statement | Derived Math Functions | Double.NaN Field

Str Function

Returns a **String** representation of a number.

```
Public Shared Function Str(ByVal Number As Object) As String
```

Parameter

Number
Required. An **Object** containing any valid numeric expression.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentNullException	5	*Number* is not specified.
InvalidCastException	5	*Number* is not a numeric type .

Remarks

When numbers are converted to strings, a leading space is always reserved for the sign of *Number*. If *Number* is positive, the returned string contains a leading space, and the plus sign is implied. A negative number will include the minus sign (-) and no leading space.

Use the **Format** function to convert numeric values you want formatted as dates, times, or currency or in other user-defined formats. Unlike the **Str** function, the **Format** function doesn't include a leading space for the sign of *Number*.

> **Note** The **Str** function recognizes only the period (**.**) as a valid decimal separator. If different decimal separators are used (for example, in international applications), use the **CStr** function to convert a number to a string.

Example

This example uses the **Str** function to return a **String** representation of a number. When a positive number is converted to a string, a leading space is always reserved for its sign.

```
Dim MyString As String
MyString = Str(459)   ' Returns " 459".
MyString = Str(-459.65)   ' Returns "-459.65".
MyString = Str(459.001)   ' Returns " 459.001".
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Conversion

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Format Function | Type Conversion Functions | Val Function | ArgumentNullException Class | InvalidCastException Class

StrComp Function

Returns -1, 0, or 1, based on the result of a string comparison.

```
Public Shared Function StrComp( _
   ByVal String1 As String, _
   ByVal String2 As String, _
   <Microsoft.VisualBasic.OptionCompareAttribute> _
   Optional ByVal Compare As Microsoft.VisualBasic.CompareMethod _
) As Integer
```

Parameters

String1
Required. Any valid **String** expression.
String2
Required. Any valid **String** expression.
Compare
Optional. Specifies the type of string comparison. If *compare* is omitted, the **Option Compare** setting determines the type of comparison.

Settings

The *Compare* argument settings are:

Constant	Description
Binary	Performs a binary comparison, based on a sort order derived from the internal binary representations of the characters.
Text	Performs a text comparison, based on a case-insensitive text sort order determined by your system's **LocaleID** value.

Return Values

The **StrComp** function has the following return values:

If	StrComp returns
String1 sorts ahead of *String2*	-1
String1 is equal to *String2*	0
String1 sorts after *String2*	1

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Compare* value is invalid.

Remarks

The strings are compared by alphanumeric sort values beginning with the first character. For further information on binary comparisons, textual comparisons, and sort order, see Option Compare Statement.

Example

This example uses the **StrComp** function to return the results of a string comparison. If the third argument is omitted, the comparison type defined in the option compare statement or project defaults is performed.

```
Dim MyStr1, MyStr2 As String
Dim MyComp As Integer
MyStr1 = "ABCD"
MyStr2 = "abcd"   ' Defines variables.
```

```
' The two strings sort equally. Returns 0
MyComp = StrComp(MyStr1, MyStr2, CompareMethod.Text)
' MyStr1 sorts after MyStr2. Returns -1.
MyComp = StrComp(MyStr1, MyStr2, CompareMethod.Binary)
' MyStr2 sorts before MyStr1. Returns 1.
MyComp = StrComp(MyStr2, MyStr1)
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Strings | String Manipulation | InStr Function | ArgumentException Class

StrConv Function

Returns a string converted as specified.

```
Public Shared Function StrConv( _
   ByVal Str As String, _
   ByVal Conversion As Microsoft.VisualBasic.VbStrConv, _
   Optional ByVal LocaleID As Integer,
) As String
```

Parameters

Str
Required. **String** expression to be converted.
Conversion
Required. **Microsoft.VisualBasic.VbStrConv** member. The enumeration value specifying the type of conversion to perform.
LocaleID
Optional. The **LocaleID** value, if different from the system **LocaleID** value. (The system **LocaleID** value is the default.)

Settings

The *Conversion* argument settings are:

Enumeration member	Description
VbStrConv.None	Performs no conversion
VbStrConv.LinguisticCasing	Uses linguistic rules for casing, rather than File System (default). Valid with UpperCase and LowerCase only.
VbStrConv.UpperCase	Converts the string to uppercase characters.
VbStrConv.LowerCase	Converts the string to lowercase characters.
VbStrConv.ProperCase	Converts the first letter of every word in string to uppercase.
VbStrConv.Wide*	Converts narrow (half-width) characters in the string to wide (full-width) c haracters.
VbStrConv.Narrow*	Converts wide (full-width) characters in the string to narrow (half-width) c haracters.
VbStrConv.Katakana**	Converts Hiragana characters in the string to Katakana characters.
VbStrConv.Hiragana**	Converts Katakana characters in the string to Hiragana characters.
VbStrConv.SimplifiedChinese*	Converts Traditional Chinese characters to Simplified Chinese.
VbStrConv.TraditionalChinese*	Converts Simplified Chinese characters to Traditional Chinese.

* Applies to Asian locales.
** Applies to Japan only.

> **Note** These constants are specified in the .NET common language runtime. As a result, they may be used anywhere in your code in place of the actual values. Most can be combined, for example, `UpperCase + Wide`, except when they are mutually exclusive, for example, `VbStrConv.Wide + VbStrConv.Narrow`.

The following are valid word separators for proper casing: Null (**Chr$(0)**), horizontal tab (**Chr$(9)**), linefeed (**Chr$(10)**), vertical tab (**Chr$(11)**), form feed (**Chr$(12)**), carriage return (**Chr$(13)**), space (single-byte character set) (**Chr$(32)**). The actual value for a space, which can be full or half width, varies by country/region for East Asian cultures.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	Unsupported *LocaleID, Conversion* < 0 or > 2048, or unsupported conversion for specif ied locale.

Remarks

The constants **VbStrConv.Wide**, **VbStrConv.Narrow**, **VbStrConv.Simplified Chinese**, **VbStrConv.Traditional Chinese**, **VbStrConv.Katakana**, and **VbStrConv.Hiragana** can cause run-time errors when used in locales where they do not apply, but not always: the constants **VbStrConv.Katakana** and **VbStrConv.Hiragana** can be used in a non-Japanese system with the Japanese Language Pack installed. In addition, use of the constants **VbStrConv.Wide** and **VbStrConv.Narrow** is supported on any system with an East Asian language installed.

Example

This example converts text into all lowercase letters.

```
Dim sText, sNewText As String
sText = "Hello World"
sNewText = StrConv(sText, VbStrConv.LowerCase)
Debug.WriteLine (sNewText)   ' Outputs "hello world".
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Chr, ChrW Functions | String Data Type | Type Conversion Functions | ArgumentException Class

StrDup Function

Returns a string or object consisting of the specified character repeated the specified number of times.

```
Public Shared Function StrDup( _
   ByVal Number As Integer, _
   ByVal Character As { Char | String } _
) As String
```

-or-

```
Public Shared Function StrDup( _
   ByVal Number As Integer, _
   ByVal Character As Object _
) As Object
```

Parameters

Number
Required. **Integer** expression. The length to the string to be returned.

Character
Required. Any valid **Char**, **String**, or **Object** expression. Only the first character of the expression will be used. If Character is of type Object, it must contain either a **Char** or a **String** value.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Number* < 0 or *Character* type is invalid .
ArgumentNullException	5	*Character* is **Nothing.**

Remarks

This function returns a **String** made up of repeated characters. The character that makes up the string is the first character in the *Character* argument, and it is duplicated *Number* number of times.

Example

This example uses the **StrDup** function to return a string of duplicated characters.

```
Dim aString As String = "Wow! What a string!"
Dim aObject As New Object()
Dim myString As String
aObject = "This is a String contained within an Object"
myString = StrDup(5, "P")   ' Returns "PPPPP"
myString = StrDup(10, aString)   ' Returns "WWWWWWWWWW"
myString = StrDup(6, aObject)   ' Returns "TTTTTT"
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

SPC Function | ArgumentException Class | ArgumentNullException Class

StrReverse Function

Returns a string in which the character order of a specified string is reversed.

```
Public Function StrReverse(ByVal Expression As String) As String
```

Parameters

Expression
Required. String expression whose characters are to be reversed. If *Expression* is a zero-length string (""), a zero-length string is returned.

Example

```
Dim myString As String = "ABCDEFG"
Dim revString As String
' Returns "GFEDCBA"
revString = StrReverse(myString)
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

InStrRev Function

Switch Function

Evaluates a list of expressions and returns an **Object** value of an expression associated with the first expression in the list that is **True**.

```
Public Function Switch( _
   ByVal ParamArray VarExpr() As Object _
) As Object
```

Parameter

VarExpr()
Required. **Object** parameter array. Must have an even number of elements. You can supply a list of **Object** variables or expressions separated by commas, or a single-dimensional array of **Object** elements.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	Number of arguments is odd.

Remarks

The **Switch** function argument *VarExpr* consists of paired expressions and values. The **Switch** function evaluates the expressions from lowest to highest subscript in *VarExpr*, and returns the value associated with the first expression that evaluates to **True**. For example, if *VarExpr(0)* is **True**, **Switch** returns *VarExpr(1)*, and if *VarExpr(0)* is **False** but *VarExpr(2)* is **True**, **Switch** returns *VarExpr(3)*, and so on.

If you do not supply the *VarExpr* argument, **Switch** returns **Nothing**. If the number of elements in *VarExpr* is not divisible by two, an **ArgumentException** error occurs.

> **Note** The expressions in the argument list can include function calls. As part of preparing the argument list for the call to **Switch**, the Visual Basic compiler calls every function in every expression. This means that you cannot rely on a particular function not being called if an expression earlier in the argument list is **True**.

Example

This example uses the **Switch** function to return the name of a language that matches the name of a city. It requires that **Option Strict** be **Off**.

```
Function MatchUp (CityName As String) As String
   Return Microsoft.VisualBasic.Switch(CityName = "London", "English", _
      CityName = "Rome", "Italian", CityName = "Paris", "French")
End Function
```

Since the **System.Diagnostics** namespace contains a class called **Switch**, a call to the **Switch** function must be qualified with the **Microsoft.VisualBasic** namespace.

Requirements

Namespace: Microsoft.VisualBasic

Module: Interaction

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Choose Function | IIf Function | Select...Case Statements | Switch Class

SYD Function

Returns a **Double** specifying the sum-of-years digits depreciation of an asset for a specified period.

```
Function SYD( _
   ByVal Cost As Double, _
   ByVal Salvage As Double, _
   ByVal Life As Double, _
   ByVal Period As Double _
) As Double
```

Parameters

Cost
Required. **Double** specifying initial cost of the asset.
Salvage
Required. **Double** specifying value of the asset at the end of its useful life.
Life
Required. **Double** specifying length of the useful life of the asset.
Period
Required. **Double** specifying period for which asset depreciation is calculated.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Salvage* < 0, *Period* > *Life*, or *Period* <=0 .

Remarks

The *Life* and *Period* arguments must be expressed in the same units. For example, if *Life* is given in months, *Period* must also be given in months. All arguments must be positive numbers.

Example

This example uses the **SYD** function to return the depreciation of an asset for a specified period given the asset's initial cost (`InitCost`), the salvage value at the end of the asset's useful life (`SalvageVal`), and the total life of the asset in years (`LifeTime`). The period in years for which the depreciation is calculated is `PDepr`.

```
Sub TestSYD()
   Dim InitCost, SalvageVal, MonthLife, DepYear, LifeTime, Pdepr As Double
   Dim Fmt As String = "###,##0.00"   ' Define money format.
   Const YEARMONTHS As Integer = 12  ' Number of months in a year.
   InitCost = CDbl(InputBox("What's the initial cost of the asset?"))
   SalvageVal = CDbl(InputBox("What's the asset's value at the end of its life?"))
   MonthLife = CDbl(InputBox("What's the asset's useful life in months?"))
   Do While MonthLife < YEARMONTHS   ' Ensure period is >= 1 year.
      MsgBox("Asset life must be a year or more.")
      MonthLife = CDbl(InputBox("What's the asset's useful life in months?"))
   Loop
   LifeTime = MonthLife / YEARMONTHS   ' Convert months to years.
   If LifeTime <> Int(MonthLife / YEARMONTHS) Then
      LifeTime = Int(LifeTime + 1)   ' Round up to nearest year.
   End If
   DepYear = CInt(InputBox("For which year do you want depreciation?"))
   Do While DepYear < 1 Or DepYear > LifeTime
      MsgBox("You must enter at least 1 but not more than " & LifeTime)
      DepYear = CInt(InputBox("For what year do you want depreciation?"))
   Loop
   Pdepr = SYD(InitCost, SalvageVal, LifeTime, DepYear)
   MsgBox("The depreciation for year " & DepYear & " is " & Format(Pdepr, Fmt) & ".")
End Sub
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Financial

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

SystemTypeName Function

Returns a **String** value containing the system data type name of a variable.

```
Public Function SystemTypeName(ByVal VbName As String) As String
```

Parameter

VbName
Required. A **String** variable containing a Visual Basic .NET type name.

Remarks

SystemTypeName returns the fully qualified common language runtime type name corresponding to the Visual Basic type name. For example, if *VbName* contains "Date", **SystemTypeName** returns "System.DateTime". If **SystemTypeName** does not recognize the value of *VbName*, it returns **Nothing** (not the string "Nothing").

Example

This example uses the **SystemTypeName** function to return data type names for several variables.

```
Dim VbLongName As String = "Long"
Dim VbDateName As String = "Date"
Dim VbBadName As String = "Number"
Dim MySysName As String
MySysName = SystemTypeName(VbLongName)   ' Returns "System.Int64".
MySysName = SystemTypeName(VbDateName)   ' Returns "System.DateTime".
MySysName = SystemTypeName(VbBadName)   ' Returns Nothing.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Information

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Data Type Summary | String Data Type | VbTypeName Function

TAB Function

Used with the **Print** or **PrintLine** functions to position output.

```
Public Overloads Function TAB() As TABInfo
```

-or-

```
Public Overloads Function TAB(ByVal Column As Short) As TABInfo
```

Parameters

Column
Optional. The column number moved to before displaying or printing the next expression in a list. If omitted, **TAB** moves the insertion point to the beginning of the next print zone.

Remarks

If the current print position on the current line is greater than *Column*, **TAB** skips to the column value equal to *Column* on the next output line. If *Column* is less than 1, **TAB** moves the print position to column 1. If *Column* is greater than the output line width, **TAB** calculates the next print position using the formula:

```
Column Mod width
```

For example, if *width* is 80 and you specify **TAB(**90**)**, the next print will start at column 10 (the remainder of 90/80). If *Column* is less than the current print position, printing begins on the next line at the calculated print position. If the calculated print position is greater than the current print position, printing begins at the calculated print position on the same line.

The leftmost print position on an output line is always 1. When you use the **Print** or **PrintLine** functions to print to files, the rightmost print position is the current width of the output file, which you can set using the **FileWidth** function.

The **TAB** function can also be used with the **WriteLine** function. It cannot be used with **System.Debug.WriteLine** or **System.Console.WriteLine**.

> **Note** Make sure your tabular columns are wide enough to accommodate wide letters.

Example

This example uses the **TAB** function to position output in a file and in the **Output** window.

```
FileOpen(1, "TESTFILE", OpenMode.Output) ' Open file for output.
' The second word prints at column 20.
Print(1, "Hello", TAB(20), "World.")
' If the argument is omitted, cursor is moved to the next print zone.
Print(1, "Hello", TAB(), "World")
FileClose(1)
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Math Functions

The math functions in Visual Basic 6 have been replaced by equivalent methods in the **System.Math** class of the .NET Framework.

Remarks

The .NET Framework math methods are functionally identical to their Visual Basic 6 counterparts, although some have slightly different names. For example, the .NET Framework equivalent of the Visual Basic 6 Atn function is **Atan**. The following table lists the Visual Basic 6 math function names and the equivalent .NET Framework methods.

Visual Basic 6 function	Visual Basic .NET method	Description
Abs	Math.Abs Method	Returns the absolute value of a specified number.
Atn	Math.Atan Method	Returns a **Double** value containing the angle whose tangent is the specified number.
Cos	Math.Cos Method	Returns a **Double** value containing the cosine of the specified angle.
Exp	Math.Exp Method	Returns a **Double** value containing e (the base of natural logarithms) raised to the specified power.
Log	Math.Log Method	Returns a **Double** value containing the logarithm of a specified number. This method is overloaded and can return either the natural (base e) logarithm of a specified number or the logarithm of a specified number in a specified base.
Round	Math.Round Method	Returns a **Double** value containing the number nearest the specified value. Additional round functions are available as methods of the intrinsic types such as Decimal.Round Method.
Sgn	Math.Sign Method	Returns an **Integer** value indicating the sign of a number.
Sin	Math.Sin Method	Returns a **Double** value specifying the sine of an angle.
Sqr	Math.Sqrt Method	Returns a **Double** value specifying the square root of a number.
Tan	Math.Tan Method	Returns a **Double** value containing the tangent of an angle.

In addition, the .NET Framework math class provides constants and other static methods for trigonometric, logarithmic, and other common mathematical functions. All of these can be used in a Visual Basic program.

To use these functions without qualification, import the **System.Math** namespace into your project by adding the following code to the top of the source code:

```
Imports System.Math
```

Requirements

Class: Math Class

Abs Example

This example uses the **Abs** method of the **Math** class to compute the absolute value of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyNumber As Double
```

```
MyNumber = Abs(50.3)    ' Returns 50.3.
MyNumber = Abs(-50.3)   ' Returns 50.3.
```

Atan Example

This example uses the **Atan** method of the **Math** class to calculate the value of pi.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim pi As Double
pi = 4 * Atan(1)   ' Calculate the value of pi.
```

Cos Example

This example uses the **Cos** method of the **Math** class to return the cosine of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MySecant As Double
MyAngle = 1.3   ' Define angle in radians.
MySecant = 1 / Cos(MyAngle)   ' Calculate secant.
```

Exp Example

This example uses the **Exp** method of the **Math** class to return *e* raised to a power.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyHSin As Double
' Define angle in radians.
MyAngle = 1.3
' Calculate hyperbolic sine.
MyHSin = (Exp(MyAngle) - Exp(-1 * MyAngle)) / 2
```

Log Example

This example uses the **Log** method of the **Math** class to return the natural logarithm of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyLog As Double
' Define angle in radians.
MyAngle = 1.3
' Calculate inverse hyperbolic sine.
MyLog = Log(MyAngle + Sqrt(MyAngle * MyAngle + 1))
```

Round Example

This example uses the **Round** method of the **Math** class to round a number to the nearest integer.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyVar1 As Double = 2.8
Dim MyVar2 As Double
MyVar2 =Round(MyVar1)   ' Returns 3.
```

Sign Example

This example uses the **Sign** method of the **Math** class to determine the sign of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyVar1, MyVar2, MyVar3 As Double
Dim MySign As Integer
MyVar1 = 12
MyVar2 = -2.4
MyVar3 = 0
MySign = Sign(MyVar1)   ' Returns 1.
MySign = Sign(MyVar2)   ' Returns -1.
MySign = Sign(MyVar3)   ' Returns 0.
```

Sin Example

This example uses the **Sin** method of the **Math** class to return the sine of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyCosecant As Double
MyAngle = 1.3   ' Define angle in radians.
MyCosecant = 1 / Sin(MyAngle)   ' Calculate cosecant.
```

Sqrt Example

This example uses the **Sqrt** method of the **Math** class to calculate the square root of a number.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MySqr As Double
MySqr = Sqrt(4)    ' Returns 2.
MySqr = Sqrt(23)   ' Returns 4.79583152331272.
MySqr = Sqrt(0)    ' Returns 0.
MySqr = Sqrt(-4)   ' Returns NaN (not a number).
```

Tan Example

This example uses the **Tan** method of the **Math** class to return the tangent of an angle.

```
Imports System.Math
' Code will not compile unless placed within a Sub or Function
Dim MyAngle, MyCotangent As Double
MyAngle = 1.3   ' Define angle in radians.
MyCotangent = 1 / Tan(MyAngle)   ' Calculate cotangent.
```

Requirements

Namespace: System.Math

Assembly: mscorlib (in mscorlib.dll)

See Also

Rnd Function | Randomize Statement | Derived Math Functions | Double.NaN Field

TimeSerial Function

Returns a **Date** value representing a specified hour, minute, and second, with the date information set relative to January 1 of the year 1.

```
Public Function TimeSerial( _
   ByVal Hour As Integer, _
   ByVal Minute As Integer, _
   ByVal Second As Integer _
) As DateTime
```

Parameters

Hour
Required. **Integer** expression from 0 through 23. However, values outside this range are also accepted.

Minute
Required. **Integer** expression from 0 through 59. However, values outside this range are also accepted. The value of *Minute* is added to the calculated hour, so a negative value specifies minutes before that hour.

Second
Required. **Integer** expression from 0 through 59. However, values outside this range are also accepted. The value of *Second* is added to the calculated minute, so a negative value specifies seconds before that minute.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	Argument is outside the range -2,147,483,648 through 2,147,483,647
ArgumentOutOfRangeException	9	Calculated time is less than negative 24 hours.

Remarks

The following example demonstrates negative, zero, and positive argument values. Here, the **TimeSerial** function returns a time representing 15 minutes before three hours before noon, or 8:45:00 A.M.:

```
Dim AlarmTime As Date = TimeSerial(12 - 3, -15, 0)
```

If either *Minute* or *Second* exceeds its normal range, it is applied to the next larger unit as appropriate. For example, if you specify 75 minutes, it is evaluated as one hour and 15 minutes. If any argument is outside the range -2,147,483,648 through 2,147,483,647, an **ArgumentException** error occurs.

TimeSerial reduces the total seconds modulo 86,400, which is the number of seconds in a day. Therefore, the returned time is always between 00:00:00 and 23:59:59.

The **Date** data type includes date components. **TimeSerial** sets all of these to 1, so the returned value represents the first day of the year 1. However, if the values of the arguments cause the calculated time to exceed 24 hours, the day is incremented as necessary. In the following example, the values of *Hour* and *Minute* result in a combined time of more than 24 hours.

```
MsgBox(TimeSerial(23, 75, 0))  ' Displays "1/2/0001 12:15:00 AM"
```

If the values of the arguments result in a negative calculated time, the date information is set to 1/1/0001 and the time information is adjusted to be between 00:00:00 and 23:59:59. However, if the calculated time is less than negative 24 hours, an **ArgumentOutOfRangeException** error occurs.

Since every **Date** value is supported by a **DateTime** structure, its methods give you additional options in assembling a **Date** value. For example, you can employ one of the overloaded **DateTime** constructors to populate a **Date** variable using the desired combination of components. The following example sets `NewDateTime` to May 6, 1978 at one tenth of a second before 8:30 in the morning:

```
Dim NewDateTime As Date = New Date(1978, 5, 6, 8, 29, 59, 900)
```

Example

This example uses the **TimeSerial** function to return a time for the specified hour, minute, and second.

```
Dim MyTime As Date
MyTime = TimeSerial(16, 35, 17)   ' Return the time in a Date data type.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: DateAndTime

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

DateSerial Function | DateValue Function | Hour Function | Minute Function | Now Property | Second Function | TimeValue Function | System Namespace | DateTime Structure | ArgumentOutOfRangeException Class | ArgumentOutOfRangeException

TimeValue Function

Returns a **Date** value containing the time information represented by a string, with the date information set to January 1 of the year 1.

```
Public Function TimeValue(ByVal StringTime As String) As DateTime
```

Parameter

StringTime
Required. **String** expression representing a date/time value from 00:00:00 on January 1 of the year 1 through 23:59:59 on December 31, 9999.

Exceptions/Errors

Exception type	Error number	Condition
InvalidCastException	13	*StringTime* includes invalid time informatio n.

Remarks

You can enter valid times using a 12-hour or 24-hour clock. For example, `"2:24 P.M."` and `"14:24"` are both valid *StringTime* arguments.

If the *StringTime* argument includes date information, **TimeValue** does not include it in the returned value. However, if *StringTime* includes invalid time information such as "January 32," an **InvalidCastException** error occurs.

Example

This example uses the **TimeValue** function to convert a string to a time. You can also use date literals to directly assign a time to a **Date** variable.

```
Dim MyTime As Date
MyTime = TimeValue("4:35:17 PM")   ' Return the time in a Date data type.
MyTime = TimeValue(#4:35:17 PM#)   ' Return the time in a Date data type.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: DateAndTime

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

DateSerial Function | DateValue Function | Hour Function | Minute Function | Now Property | Second Function | TimeSerial Function | System Namespace | DateTime Structure | InvalidCastException Class

LTrim, RTrim, and Trim Functions

Returns a string containing a copy of a specified string with no leading spaces (**LTrim**), no trailing spaces (**RTrim**), or no leading or trailing spaces (**Trim**).

```
Public Shared Function LTrim(ByVal Str As String) As String
Public Shared Function RTrim(ByVal Str As String) As String
Public Shared Function Trim(ByVal Str As String) As String
```

Parameter

Str
Required. Any valid **String** expression.

Example

This example uses the **LTrim** function to strip leading spaces and the **RTrim** function to strip trailing spaces from a string variable. It uses the **Trim** function to strip both types of spaces.

```
Dim MyString, TrimString As String
MyString = "  <-Trim->  "   ' Initializes string.
TrimString = LTrim(MyString)   ' TrimString = "<-Trim->  ".
TrimString = RTrim(MyString)   ' TrimString = "  <-Trim->".
TrimString = LTrim(RTrim(MyString))   ' TrimString = "<-Trim->".
' Using the Trim function alone achieves the same result.
TrimString = Trim(MyString)   ' TrimString = "<-Trim->".
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Left Function | Right Function

TypeName Function

Returns a **String** value containing data type information about a variable.

```
Public Function TypeName(ByVal VarName As Object) As String
```

Parameter

VarName
Required. **Object** variable. If **Option Strict** is **Off**, you can pass a variable of any data type except a structure.

Remarks

The following table shows the **String** values returned by **TypeName** for different contents of *VarName*.

***VarName* contents**	**String returned**
16-bit **True** or **False** value type	"Boolean"
8-bit binary value type	"Byte"
16-bit character value type	"Char"
64-bit date and time value type	"Date"
Reference type indicating missing or nonexistent data	"DBNull"
128-bit fixed point numeric value type	"Decimal"
64-bit floating point numeric value type	"Double"
32-bit integer value type	"Integer"
Reference type pointing to an unspecialized object	"Object"
Reference type pointing to a specialized object created from class *<objectclass>*	"*<objectclass>*"
64-bit integer value type	"Long"
Reference type with no object currently assigned to it	"Nothing"
16-bit integer value type	"Short"
32-bit floating point numeric value type	"Single"
Reference type pointing to a string of 16-bit characters	"String"

If *VarName* is an array, the returned string can be any one of the strings in the preceding table with empty parentheses appended. For example, if *VarName* points to an array of integers, **TypeName** returns "Integer()".

When **TypeName** returns the name of a reference type such as a class, it only returns the simple name, not the qualified name. For example, if *VarName* points to an object of class **System.Drawing.Printing.PaperSource**, **TypeName** returns "PaperSource".

Example

This example uses the **TypeName** function to return data type information about several variables.

```
Dim MyType As String
Dim StrVar As String = "MyString"
Dim DecVar As Decimal
Dim IntVar, ArrayVar(5) As Integer
MyType = TypeName(StrVar)   ' Returns "String".
MyType = TypeName(IntVar)   ' Returns "Integer".
MyType = TypeName(ArrayVar)   ' Returns "Integer()".
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Information

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Data Type Summary | IsArray Function | IsDate Function | IsDBNull Function | IsError Function | IsNothing Function | IsNumeric Function | IsReference Function | Object Data Type

UBound Function

Returns the highest available subscript for the indicated dimension of an array.

```
Public Function UBound( _
   ByVal Array As System.Array, _
   Optional ByVal Rank As Integer = 1 _
) As Integer
```

Parameters

Array
Required. Array of any data type. The array in which you want to find the highest possible subscript of a dimension.

Rank
Optional. **Integer**. The dimension for which the highest possible subscript is to be returned. Use 1 for the first dimension, 2 for the second, and so on. If *Rank* is omitted, 1 is assumed.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentNullException	9	*Array* is **Nothing**
RankException	9	*Rank* is less than 1 or *Rank* is greater than the rank of array.

Remarks

Since array subscripts start at 0, the length of a dimension is greater by one than the highest available subscript for that dimension.

For an array with the following dimensions, **UBound** returns the values in the following table:

```
Dim A(100, 5, 4) As Byte
```

Call to UBound	Return value
`UBound(A, 1)`	100
`UBound(A, 2)`	5
`UBound(A, 3)`	4

You can use **UBound** to determine the total number of elements in an array, but you must adjust the value it returns to account for the fact that the subscripts start at 0. The following example calculates the total size of the array `A` in the preceding example:

```
Dim Total As Integer
Total = (UBound(A, 1) + 1) * (UBound(A, 2) + 1) * (UBound(A, 3) + 1)
```

The value calculated for `Total` is 3030, which is 101 * 6 * 5.

Example

This example uses the **UBound** function to determine the highest available subscript for the indicated dimension of an array.

```
Dim Highest, MyArray(10, 15, 20), AnyArray(6) as Integer
Highest = UBound(MyArray, 1)   ' Returns 10.
Highest = UBound(MyArray, 3)   ' Returns 20.
Highest = UBound(AnyArray)   ' Returns 6.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Information

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

LBound Function | Dim Statement | ReDim Statement | ArgumentException Class | RankException Class

UCase Function

Returns a string or character containing the specified string converted to uppercase.

```
Public Shared Function UCase(ByVal Value As Char) As Char
```

-or-

```
Public Shared Function UCase(ByVal Value As String) As String
```

Parameter

Value
Required. Any valid **String** or **Char** expression.

Remarks

Only lowercase letters are converted to uppercase; all uppercase letters and nonletter characters remain unchanged.

Example

This example uses the **UCase** function to return an uppercase version of a string.

```
Dim LowerCase, UpperCase As String
LowerCase = "Hello World 1234"   ' String to convert.
UpperCase = UCase(LowerCase)   ' Returns "HELLO WORLD 1234".
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Strings | String Manipulation | LCase Function

Lock, Unlock Functions

Controls access by other processes to all or part of a file opened using the **Open** function.

```
Public Overloads Sub Lock(ByVal FileNumber As Integer)
. . .
Public Overloads Sub Unlock(ByVal FileNumber As Integer)
```

-or-

```
Public Overloads Sub Lock(_
   ByVal FileNumber As Integer, _
   ByVal FromRecord As Long _
)
. . .
Public Overloads Sub Unlock( _
   ByVal FileNumber As Integer, _
   ByVal FromRecord As Long _
)
```

-or-

```
Public Overloads Sub Lock( _
   ByVal FileNumber As Integer, _
   ByVal FromRecord As Long, _
   ByVal ToRecord As Long _
)
. . .
Public Overloads Sub Unlock( _
   ByVal FileNumber As Integer, _
   ByVal FromRecord As Long, _
   ByVal ToRecord As Long _
)
```

Parameters

FileNumber
Required. Any valid file number.
FromRecord
Optional. Number of the first record or byte to lock or unlock.
ToRecord
Optional. Number of the last record or byte to lock or unlock.

Exceptions/Errors

Exception type	Error number	Condition
IOException	52	*FileNumber* does not exist.
IOException	54	File mode is invalid.

Remarks

The **Lock** and **Unlock** functions are used in environments where several processes might need access to the same file.

Lock and **Unlock** functions are always used in pairs. The arguments to **Lock** and **Unlock** must match exactly.

If *FromRecord* and *ToRecord* are not supplied, the lock will be for the entire file. If *FromRecord* is specified but not *ToRecord*, the single record will be locked/unlocked.

If the file has been opened for sequential input or output, **Lock** and **Unlock** affect the entire file, regardless of the range specified by *FromRecord* and *ToRecord*.

Example

This example illustrates the use of the **Lock** and **Unlock** functions. This example assumes that `people.txt` is a file containing records of the structure `Person`.

```
Structure Person
   Dim Name As String
   Dim ID As Integer
End Structure

Sub PutInLockedFile(ByVal index As Integer, ByVal onePerson As Person)
   Try
      FileOpen(1, "c:\people.txt", OpenMode.Binary)
      Lock(1)
      FilePut(index, onePerson)
      Unlock(1)
      FileClose(1)
   Catch
      ' Error recovery code here.
   End Try
End Sub
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

FileOpen Function | IOException Class

Val Function

Returns the numbers contained in a string as a numeric value of appropriate type.

```
Public Overloads Function Val(ByVal Expression As String) As Double
```

-or-

```
Public Overloads Function Val(ByVal Expression As Object) As Double
```

-or-

```
Public Overloads Function Val(ByVal Expression As Char) As Integer
```

Parameter

Expression
Required. Any valid **String** expression, **Object** variable, or **Char** value. If *Expression* is of type **Object**, its value must be convertible to **String** or an **ArgumentException** error occurs.

Exceptions/Errors

Exception type	Error number	Condition
OverflowException	6	*InputStr* is too large.
InvalidCastException	13	Number is badly formed.
ArgumentException	438	**Object** type expression not convertible to **String**.

Remarks

The **Val** function stops reading the string at the first character it cannot recognize as part of a number. Symbols and characters that are often considered parts of numeric values, such as dollar signs and commas, are not recognized. However, the function recognizes the radix prefixes `&O` (for octal) and `&H` (for hexadecimal). Blanks, tabs, and linefeed characters are stripped from the argument.

The following returns the value 1615198:

```
Val(" 1615 198th Street N.E.")
```

In the code below, **Val** returns the decimal value -1 for the hexadecimal value shown:

```
Val("&HFFFF")
```

> **Note** The **Val** function recognizes only the period (**.**) as a valid decimal separator. When different decimal separators are used, as in international applications, use **CDbl** or **CInt** instead to convert a string to a number.

Example

This example uses the **Val** function to return the numbers contained in each string. **Val** stops converting at the first character that cannot be interpreted as a numeric digit, numeric modifier, numeric punctuation, or white space.

```
Dim ValResult As Double
ValResult = Val("2457")    ' ValResult is set to 2457.
ValResult = Val(" 2 45 7")    ' ValResult is set to 2457.
ValResult = Val("24 and 57")    ' ValResult is set to 24.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Conversion

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Str Function | Type Conversion Functions | OverflowException Class | InvalidCastException Class | ArgumentException Class

VarType Function

Returns an **Integer** value containing the data type classification of a variable.

```
Public Function VarType(ByVal VarName As Object) As VariantType
```

Parameter

VarName
Required. **Object** variable. If **Option Strict** is **Off**, you can pass a variable of any data type except a structure.

Remarks

The integer value returned by **VarType** is a member of the **VariantType** enumeration.

The following table shows the values returned by **VarType** for special cases of *VarName*.

Data type represented by *VarName*	**Value returned by *VarType***
Nothing	**VariantType.Object**
DBNull	**VariantType.Null**
Enumeration	Underlying data type (**Byte**, **Short**, **Integer**, or **Long**)
Array	Bitwise OR of array element type and **VariantType.Array**
Array of arrays	Bitwise OR of **VariantType.Object** and **VariantType.Array**
Structure (**System.ValueType**)	**VariantType.UserDefinedType**
System.Exception	**VariantType.Error**
Unknown	**VariantType.Object**

Example

This example uses the **VarType** function to return data type classification information about several variables.

```
Dim MyString As String = "MyString"
Dim MyObject As Object
Dim MyNumber, MyArray(5) As Integer
Dim MyVarType As VariantType   ' Integer enumeration.
MyVarType = VarType(MyVarType)   ' Returns VariantType.Integer.
MyVarType = VarType(MyString)   ' Returns VariantType.String.
MyVarType = VarType(MyObject)   ' Returns VariantType.Object.
MyVarType = VarType(MyArray)   ' Returns the bitwise OR of
                                     ' VariantType.Array and
                                     ' VariantType.Integer.
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: Information

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Data Type Summary | Object Data Type | VariantType Enumeration

VbTypeName Function

Returns a **String** value containing the Visual Basic data type name of a variable.

```
Public Function VbTypeName(ByVal UrtName As String) As String
```

Parameter

UrtName
Required. **String** variable containing a type name used by the common language runtime.

Remarks

VbTypeName returns the Visual Basic .NET type name corresponding to the common language runtime type name. For example, if *UrtName* contains "Int32" or "System.Int32", **VbTypeName** returns "Integer". If **VbTypeName** does not recognize the value of *UrtName*, it returns **Nothing** (not the string "Nothing").

The type name in *UrtName* can be obtained from various sources, for example from the **Name** property of the **System.Type** class.

Example

This example uses the **VbTypeName** function to return data type names for several variables.

```
Dim SysDateName As String = "System.DateTime"
Dim SysShortName As String = "Int16"
Dim SysBadName As String = "Nonsense"
Dim MyVbName As String
MyVbName = VbTypeName(SysDateName)   ' Returns "Date".
MyVbName = VbTypeName(SysShortName)   ' Returns "Short".
MyVbName = VbTypeName(SysBadName)   ' Returns Nothing.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Information

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Data Type Summary | String Data Type | Type Class | SystemTypeName Function

Weekday Function

Returns an **Integer** value containing a number representing the day of the week.

```
Public Function Weekday( _
   ByVal DateValue As DateTime, _
   Optional ByVal DayOfWeek As FirstDayOfWeek = FirstDayOfWeek.Sunday _
) As Integer
```

Parameters

DateValue
Required. **Date** value for which you want to determine the day of the week.

DayOfWeek
Optional. A value chosen from the **FirstDayOfWeek** enumeration that specifies the first day of the week. If not specified, **FirstDayOfWeek.Sunday** is used.

Settings

The *DayOfWeek* argument can have one of the following settings.

Enumeration value	Value	Description
FirstDayOfWeek.System	0	First day of week specified in system settings
FirstDayOfWeek.Sunday	1	Sunday (default)
FirstDayOfWeek.Monday	2	Monday (complies with ISO standard 8601, section 3.17)
FirstDayOfWeek.Tuesday	3	Tuesday
FirstDayOfWeek.Wednesday	4	Wednesday
FirstDayOfWeek.Thursday	5	Thursday
FirstDayOfWeek.Friday	6	Friday
FirstDayOfWeek.Saturday	7	Saturday

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*DayOfWeek* is less than 0 or more than 7 .

Remarks

The value returned by the **Weekday** function corresponds to the values of the **FirstDayOfWeek** enumeration; that is, 1 indicates Sunday and 7 indicates Saturday.

If *DayOfWeek* is less than 0 or more than 7, an **ArgumentException** error occurs.

> **Note** **Weekday** uses the current calendar setting from the **CurrentCulture** property of the **CultureInfo** class in the **System.Globalization** namespace. The default **CurrentCulture** values are determined by **Control Panel** settings.

Example

This example uses the **Weekday** function to obtain the day of the week from a specified date.

```
Dim MyDate As Date
Dim MyWeekDay As Integer
MyDate = #2/12/1969#   ' Assign a date.
MyWeekDay = Weekday(MyDate)   ' MyWeekDay contains 4 because
   ' MyDate represents a Wednesday.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: DateAndTime

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Day Function | Month Function | Now Property | WeekdayName Function | Year Function | DatePart Function | System Namespace | DateTime Structure | ArgumentException Class

WeekdayName Function

Returns a **String** value containing the name of the specified weekday.

```
Public Function WeekdayName( _
   ByVal WeekDay As Integer, _
   Optional ByVal Abbreviate As Boolean = False, _
   Optional ByVal FirstDayOfWeekValue As FirstDayOfWeek = FirstDayOfWeek.System _
) As String
```

Parameters

WeekDay
Required. **Integer**. The numeric designation for the weekday, from 1 through 7; 1 indicates the first day of the week and 7 indicates the last day of the week. The identities of the first and last days depend on the setting of *FirstDayOfWeekValue*.

Abbreviate
Optional. **Boolean** value that indicates if the weekday name is to be abbreviated. If omitted, the default is **False**, which means the weekday name is not abbreviated.

FirstDayOfWeekValue
Optional. A value chosen from the **FirstDayOfWeek** enumeration that specifies the first day of the week. If not specified, **FirstDayOfWeek.System** is used.

Settings

The *FirstDayOfWeekValue* argument can have one of the following settings.

Enumeration value	Value	Description
FirstDayOfWeek.System	0	First day of week specified in system settings (default)
FirstDayOfWeek.Sunday	1	Sunday
FirstDayOfWeek.Monday	2	Monday (complies with ISO standard 8601, section 3.17)
FirstDayOfWeek.Tuesday	3	Tuesday
FirstDayOfWeek.Wednesday	4	Wednesday
FirstDayOfWeek.Thursday	5	Thursday
FirstDayOfWeek.Friday	6	Friday
FirstDayOfWeek.Saturday	7	Saturday

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*WeekDay* is less than 1 or greater than 7, o r *FirstDayOfWeekValue* is less than 0 or gr eater than 7.

Remarks

The string returned by **WeekdayName** depends not only on the input arguments, but also on the Regional Options settings specified in the Windows Control Panel.

If *WeekDay* is less than 1 or more than 7, or if *FirstDayOfWeekValue* is less than 0 or more than 7, an **ArgumentException** error occurs.

> **Note** **WeekdayName** uses the current calendar setting from the **CurrentCulture** property of the **CultureInfo** class in the **System.Globalization** namespace. The default **CurrentCulture** values are determined by **Control Panel** settings.

Requirements

Namespace: Microsoft.VisualBasic

Module: DateAndTime

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

MonthName Function | System Namespace | System.Globalization Namespace | DateTime Structure | ArgumentException Class | CultureInfo Class

Write, WriteLine Functions

Writes data to a sequential file. Data written with **Write** is usually read from a file with **Input**.

```
Public Sub Write( _
   ByVal FileNumber As Integer, _
   ByVal ParamArray Output As Object _
)
```

-or-

```
Public Sub WriteLine( _
   ByVal FileNumber As Integer, _
   ByVal ParamArray Output() As Object _
)
```

Parameters

FileNumber
Required. An **Integer** expression containing any valid file number.
Output
Optional. One or more comma-delimited expressions to write to a file.

Exceptions/Errors

Exception type	Error number	Condition
IOException	52	*FileNumber* does not exist.
IOException	54	File mode is invalid.

Remarks

If you omit *Output*, a blank line is printed to the file. Multiple expressions can be separated with a comma.

Unlike the **Print** function, the **Write** function inserts commas between items and quotation marks around strings as they are written to the file. You don't have to put explicit delimiters in the list. When **Write** is used to write data to a file, only the following data formats are supported and several universal assumptions are followed so the data can always be read and correctly interpreted using **Input**, regardless of locale:

- Numeric data is always written using the period as the decimal separator.
- For **Boolean** data, either `#TRUE#` or `#FALSE#` is printed. The **True** and **False** keywords are not translated, regardless of locale.
- Date data is written to the file using the universal date format. When either the date or the time component is missing or zero, only the part provided gets written to the file.
- Nothing is written to the file if *Output* data is empty. However, for null data, `#NULL#` is written.
- For **Error** data, the output appears as `#ERROR errorcode#`. The **Error** keyword is not translated, regardless of locale.

WriteLine inserts a newline character (that is, a carriage return–linefeed, or `Chr(13) + Chr(10)`), after it has written the final character in *Output* to the file.

You can embed quotation marks in a string by using double quotation marks, or "". For example,

```
Dim x As String = "Double quotation marks aren't ""difficult"" to handle."
```

returns a string with the value of Double quotation marks aren't "difficult" to handle.

Writing to a file with the **Write** or **WriteLine** functions requires **Append** access from the **FileIOPermissionAccess** enumeration. For more information, see FileIOPermissionAccess Enumeration.

Example

This example uses the **Write** function to write raw data to a sequential file.

```
FileOpen(1, "TESTFILE", OpenMode.Output) ' Open file for output.
Write(1, "This is a test.")  ' Print text to file.
WriteLine(1)  ' Print blank line to file.
WriteLine(1, "Zone 1", TAB(), "Zone 2")   ' Print in two print zones.
WriteLine(1, "Hello", " ", "World")     ' Separate strings with space.
WriteLine(1, SPC(5), "5 leading spaces ")    ' Print five leading spaces.
WriteLine(1, TAB(10), "Hello")   ' Print word at column 10.

' Assign Boolean, Date, and Error values.
Dim aBool As Boolean
Dim aDate As DateTime
aBool = False
aDate = DateTime.Parse("February 12, 1969")

' Dates and Booleans are translated using locale settings of
' your system.
WriteLine(1, aBool, " is a Boolean value")
WriteLine(1, aDate, " is a date")
FileClose(1)   ' Close file.
```

Smart Device Developer Notes

This function is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: FileSystem

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Input Function | FileOpen Function | Print, PrintLine Functions | File Access with Visual Basic Run-Time Functions| IOException Class

Year Function

Returns an **Integer** value from 1 through 9999 representing the year.

```
Public Function Year(ByVal DateValue As DateTime) As Integer
```

Parameter

DateValue
Required. **Date** value from which you want to extract the year.

You can also obtain the year by calling **DatePart** and specifying **DateInterval.Year** for the *Interval* argument.

Example

This example uses the **Year** function to obtain the year from a specified date. In the development environment, the date literal is displayed in short date format using the locale settings of your code.

```
Dim MyDate As Date
Dim MyYear As Integer
MyDate = #2/12/1969#   ' Assign a date.
MyYear = Year(MyDate)   ' MyYear contains 1969.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: DateAndTime

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Visual Basic Language and Run-Time Reference

Visual Basic Language

A-E Keywords

The following table contains a listing of the Visual Basic .NET language keywords.

Alias	Ansi	As	Assembly
Auto	ByRef	ByVal	Case
Default	DirectCast	Each	Else
ElseIf	End	Error	Explicit

See Also

F–O Keywords | P–Z Keywords | Visual Basic Language and Run-Time Reference

Alias

The **Alias** keyword indicates that an external procedure has another name in its DLL.

The **Alias** keyword is used in this context:

Declare Statement

See Also

Visual Basic Language Keywords

Ansi

The **Ansi** keyword indicates that strings are converted to American National Standards Institute (ANSI) values regardless of the name of the method being declared.

The **Ansi** keyword is used in this context:

Declare Statement

Smart Device Developer Notes

This keyword is not supported.

See Also

Visual Basic Language Keywords

As

The **As** keyword introduces an **As** clause, which identifies a data type.

The **As** keyword is used in these contexts:

Const Statement

Declare Statement

Delegate Statement

Dim Statement

Enum Statement

Event Statement

For...Next Statements

For Each...Next Statements

Function Statement

Property Statement

Sub Statement

Try...Catch...Finally Statements

See Also

Visual Basic Language Keywords

Assembly

The **Assembly** keyword indicates that an attribute block at the beginning of a source file applies to the entire assembly and not only to the current module.

See Also

Application of Attributes

Auto

The **Auto** keyword indicates that strings are converted according to common language runtime rules based on the name of the method being declared.

The **Auto** keyword is used in this context:

Declare Statement

Smart Device Developer Notes

This keyword is not supported.

See Also

Visual Basic Language Keywords

ByRef

The **ByRef** keyword indicates that an argument is passed in such a way that the called procedure can change the value of a variable underlying the argument in the calling code.

The **ByRef** keyword is used in these contexts:

Declare Statement

Function Statement

Sub Statement

See Also

Visual Basic Language Keywords | Argument Passing ByVal and ByRef

ByVal

The **ByVal** keyword indicates that an argument is passed in such a way that the called procedure or property cannot change the value of a variable underlying the argument in the calling code.

The **ByVal** keyword is used in these contexts:

Declare Statement

Function Statement

Property Statement

Sub Statement

See Also

Visual Basic Language Keywords | Argument Passing ByVal and ByRef

Case

The **Case** keyword introduces a value or set of values against which the value of an expression is to be tested.

The **Case** keyword is used in this context:

Select...Case Statements

See Also

Visual Basic Language Keywords

Default

The **Default** keyword identifies a property as the default property of its class.

The **Default** keyword is used in this context:

Property Statement

See Also

Visual Basic Language Keywords

DirectCast

The **DirectCast** keyword introduces a type conversion operation. You use it the same way you use the **CType** keyword, as the following example shows:

```
Dim Q As Object = 2.37   ' Requires Option Strict to be Off.
Dim I As Integer = CType(Q, Integer)   ' Succeeds.
Dim J As Integer = DirectCast(Q, Integer)   ' Fails.
```

Both keywords take an expression to be converted as the first argument, and the type to convert it to as the second argument. Both conversions fail if there is no conversion defined between the data type of the expression and the data type specified as the second argument.

The difference between the two keywords is that **CType** succeeds as long as there is a valid conversion defined between the expression and the type, whereas **DirectCast** requires the run-time type of an object variable to be the same as the specified type. If the specified type and the run-time type of the expression are the same, however, the run-time performance of **DirectCast** is better than that of **CType**.

In the preceding example, the run-time type of `Q` is **Double**. **CType** succeeds because **Double** can be converted to **Integer**, but **DirectCast** fails because the run-time type of `Q` is not already **Integer**.

DirectCast throws an **InvalidCastException** error if the argument types do not match.

See Also

Implicit and Explicit Conversions | InvalidCastException Class

Each

The **Each** keyword specifies the loop variable to be used in a **For Each** loop.

The **Each** keyword is used in this context:

For Each...Next Statements

See Also

Visual Basic Language Keywords

Else

The **Else** keyword introduces a group of statements to be executed if no other conditional group of statements has been executed.

The **Else** keyword is used in these contexts:

If...Then...Else Statements

Select...Case Statements

See Also

Visual Basic Language Keywords

ElseIf

The **ElseIf** keyword introduces a condition to be tested if the previous conditional test has failed.

The **ElseIf** keyword is used in this context:

If...Then...Else Statements

See Also

Visual Basic Language Keywords

End

When used with an additional keyword, **End** indicates the end of the definition of a procedure or block.

```
End Class
End Enum
End Function
End Get
End If
End Interface
End Module
End Namespace
End Property
End Select
End Set
End Structure
End Sub
End SyncLock
End Try
End While
End With
```

Parts

End
Required. Terminates the definition of the procedure or block.

Class
Required to end a **Class** definition.

Enum
Required to end an **Enum** definition.

Function
Required to end a **Function** procedure definition. If execution encounters an **End Function** statement, control is returned to the calling code.

Get
Required to end a **Property** procedure definition to retrieve the property's value. If execution encounters an **End Get** statement, control is returned to the statement requesting the value.

If
Required to end the definition of the **If...Then...Else** statements.

Interface
Required to end an **Interface** definition.

Module
Required to end a **Module** definition.

Namespace
Required to end a **Namespace** definition.

Property
Required to end a **Property** definition.

Select
Required to end the definition of the **Select...Case** statements.

Set
Required to end a **Property** procedure definition to set the property's value. If execution encounters an **End Set** statement, control is returned to the statement setting the value.

Structure
Required to end a **Structure** definition.

Sub
Required to end a **Sub** procedure definition. If execution encounters an **End Sub** statement, control is returned to the calling code.

SyncLock
Required to end the definition of the **SyncLock...End SyncLock** statements.

Try
Required to end the definition of the **Try...Catch...Finally** statements.

While

Required to end the definition of the **While** statement.

With

Required to end the definition of the **With...End With** statements.

Remarks

The **End** statement, without an additional keyword, terminates execution immediately.

Smart Device Developer Notes

The **End** statement, without an additional keyword, is not supported.

See Also

End Statement | Class Statement | Enum Statement | Function Statement | If...Then...Else Statements | Interface Statement | Module Statement | Namespace Statement | Property Statement | Select...Case Statements | Structure Statement | Sub Statement | SyncLock Statement | Try...Catch...Finally Statements | While...End While Statements | With...End With Statements

Error

The **Error** keyword either simulates or responds to a run-time error.

The **Error** keyword is used in these contexts:

Error Statement

On Error Statement

See Also

Visual Basic Language Keywords | Exception Handling

Explicit

The **Explicit** keyword is used in this context:

Option Explicit Statement

See Also

Visual Basic Language Keywords

F-O Keywords

The following table contains a listing of the Visual Basic .NET language keywords.

False	For	Friend	Handles
In	Is	Lib	Loop
Me	Module	MustInherit	MustOverride
MyBase	MyClass	New	Next
Nothing	NotInheritable	NotOverridable	Off
On	Option	Optional	Overloads
Overridable	Overrides		

See Also

A–E Keywords | P–Z Keywords | Visual Basic Language and Run-Time Reference

False

The **False** keyword represents a Boolean value that fails a conditional test.

See Also

Boolean Data Type | True

For

The **For** keyword introduces a loop that is iterated with different values of a loop variable.

The **For** keyword is used in these contexts:

For...Next Statements

For Each...Next Statements

See Also

Visual Basic Language Keywords

Friend

The **Friend** keyword confers friend access on one or more declared programming elements. Friend elements are accessible from within the program that contains their declaration and from anywhere else in the same assembly.

The **Friend** keyword can be used in conjunction with the **Protected** keyword in the same declaration. This combination confers both friend and protected access on the declared elements, so they are accessible from the same assembly, from their own class, and from any derived classes.

The **Friend** keyword is used in these contexts:

Class Statement

Const Statement

Declare Statement

Delegate Statement

Dim Statement

Enum Statement

Event Statement

Function Statement

Interface Statement

Module Statement

Property Statement

Structure Statement

Sub Statement

See Also

Protected | Accessibility | Procedures | Structures: Your Own Data Types | Understanding Classes

Handles

The **Handles** keyword is used to declare that a procedure handles a specified event.

```
proceduredeclaration Handles event
```

Parts

proceduredeclaration
The **Sub** procedure declaration for the procedure that will handle the event.

event
The name of the event being handled. This event must be raised by either the base class for the current class, or by an object declared using the **WithEvents** keyword.

Remarks

Use the **Handles** keyword at the end of a procedure declaration to cause it to handle events raised by an object variable declared using the **WithEvents** keyword. The **Handles** keyword can also be used in a derived class to handle events from a base class.

Example

```
Public Class ContainerClass
   WithEvents Obj As New Class1()  ' Module or class level declaration.

   Public Class Class1
      Public Event Ev_Event()      ' Declare an event.
      Sub CauseSomeEvent()
         RaiseEvent Ev_Event()     ' Raise an event.
      End Sub
   End Class

   Sub EventHandler() Handles Obj.Ev_Event
      MsgBox("EventHandler caught event.")   ' Handle the event.
   End Sub

' Call the TestEvents procedure from an instance of the ContainerClass
' class to test the Ev_Event event and the event handler.
   Public Sub TestEvents()
      Obj.CauseSomeEvent()
   End Sub
End Class
```

The following example demonstrates how a derived class can use the **Handles** statement to handle an event from a base class.

```
Public Class BaseClass
   Event Ev1() ' Declare an event.
End Class
Class DerivedClass
   Inherits BaseClass
   Sub TestEvents() Handles MyBase.Ev1
      ' Add code to handle this event.
   End Sub
End Class
```

See Also

WithEvents | AddHandler Statement | RemoveHandler Statement | Events and Event Handlers

Implements

The **Implements** keyword indicates that a class or structure member is providing the implementation for a member defined in an interface. The **Implements** keyword is not the same as the **Implements** statement.

If a class or structure implements an interface, it must include the **Implements** statement immediately after the **Class** or **Structure** statement, and it must implement all the members defined by the interface.

The **Implements** keyword is used in these contexts:

Event Statement

Function Statement

Property Statement

Sub Statement

See Also

Implements Statement | Implements Keyword | Interface Statement | Class Statement | Structure Statement

In

The **In** keyword specifies the group the loop variable is to traverse in a **For Each** loop.

The **In** keyword is used in this context:

For Each...Next Statements

See Also

Visual Basic Language Keywords

Is

The **Is** keyword introduces an **Is** clause that makes a comparison.

The **Is** keyword is used in these contexts:

Is Operator

Select...Case Statements

See Also

Visual Basic Language Keywords

Lib

The **Lib** keyword identifies the library containing an external procedure.

The **Lib** keyword is used in this context:

Declare Statement

See Also

Visual Basic Language Keywords

Loop

The **Loop** keyword terminates a loop introduced with a **Do** statement.

The **Loop** keyword is used in this context:

Do...Loop Statements

See Also

Visual Basic Language Keywords

Me

The **Me** keyword provides a way to refer to the specific instance of a class or structure in which the code is currently executing. **Me** behaves like either an object variable or a structure variable referring to the current instance. Using **Me** is particularly useful for passing information about the currently executing instance of a class or structure to a procedure in another class, structure, or module. For example, suppose you have the following procedure in a module:

```
Sub ChangeFormColor(FormName As Form)
   Randomize()
   FormName.BackColor = Color.FromArgb(Rnd() * 256, Rnd() * 256, Rnd() * 256)
End Sub
```

You can call this procedure and pass the current instance of the **Form** class as an argument using the following statement:

```
ChangeFormColor(Me)
```

The **Me** keyword is used in these contexts:

Class Statement

Structure Statement

See Also

Object Variable Assignment | MyBase | MyClass

Module

The **Module** keyword indicates that an attribute block at the beginning of a source file applies only to the current module and not to the entire assembly. The **Module** keyword is not the same as the **Module** statement.

See Also

Application of Attributes | Module Statement

MustInherit

The **MustInherit** keyword specifies that a class cannot be instantiated and can be used only as a base class.

The **MustInherit** keyword is used in this context:

Class Statement

See Also

Visual Basic Language Keywords

MustOverride

The **MustOverride** keyword specifies that a property or procedure in a base class must be overridden in a derived class before it can be used.

The **MustOverride** keyword is used in these contexts:

Function Statement

Property Statement

Sub Statement

See Also

Visual Basic Language Keywords | Shadowing

MyBase

The **MyBase** keyword behaves like an object variable referring to the base class of the current instance of a class. **MyBase** is commonly used to access base class members that are overridden or shadowed in a derived class. In particular, **MyBase.New** is used to explicitly call a base class constructor from a derived class constructor.

It is invalid to use **MyBase** to call **MustOverride** base methods.

See Also

Inheritance Basics | Me | MyClass | New

MyClass

MyClass behaves like an object variable referring to the current instance of a class as originally implemented. **MyClass** is similar to **Me**, but all method calls on it are treated as if the method were **NotOverridable**. Therefore, the method being called is not affected by overriding in a derived class. The following example compares **Me** and **MyClass**.

```
Class BaseClass
   Public Overridable Sub MyMethod()
      MsgBox("Base class string")
   End Sub
   Public Sub UseMe()
      Me.MyMethod()   ' Use calling class's version, even if an override.
   End Sub
   Public Sub UseMyClass()
      MyClass.MyMethod()   ' Use this version and not any override.
   End Sub
End Class
Class DerivedClass : Inherits BaseClass
   Public Overrides Sub MyMethod()
      MsgBox("Derived class string")
   End Sub
End Class
Class TestClasses
   Sub StartHere()
      Dim TestObj As DerivedClass = New DerivedClass()
      TestObj.UseMe()   ' Displays "Derived class string".
      TestObj.UseMyClass()   ' Displays "Base class string".
   End Sub
End Class
```

Even though `DerivedClass` overrides `MyMethod`, the **MyClass** keyword in `UseMyClass` nullifies the effects of overriding, and the compiler resolves the call to the base class version of `MyMethod`.

MyClass cannot not be used inside a **Shared** method, but you can use it inside an instance method to access a shared member of a class.

See Also

Inheritance Basics | Me | MyBase

New

The **New** keyword introduces a **New** clause, which creates a new object instance. The **New** clause must specify a defined class from which the instance can be created. You can use **New** in a declaration statement or an assignment statement. When the statement is executed, it calls the constructor of the specified class, passing any arguments you have supplied:

```
Dim Obj As Object
Obj = New SomeClass("String required by constructor")
' ...
Dim MyLabel As New Label()
```

Since arrays are classes, **New** can create a new array instance:

```
Dim MyArray As Integer()
MyArray = New Integer() {0, 1, 2, 3}
```

The common language runtime throws an **OutOfMemoryException** error if there is insufficient memory to create the new instance.

The **New** keyword is used in this context:

Dim Statement

See Also

Visual Basic Language Keywords | Object Lifetime: How Objects Are Created and Destroyed | Using Constructors and Destructors | OutOfMemoryException Class

Next

The **Next** keyword either terminates a loop that is iterated with different values of a loop variable, or specifies that execution should continue with the statement following the statement that generated an error.

The **Next** keyword is used in these contexts:

For...Next Statements

For Each...Next Statements

On Error Statement

Resume Statement

See Also

Visual Basic Language Keywords

Nothing

The **Nothing** keyword represents the default value of any data type. Assigning **Nothing** to a variable sets it to the default value for its declared type. If that type contains variable members, they are all set to their default values. The following example illustrates this:

```
Public Structure MyStruct
   Public Name As String
   Public Number As Short
End Structure
Dim S As MyStruct, I As Integer, B As Boolean
S = Nothing   ' Sets S.Name to Nothing, S.Number to 0.
I = Nothing   ' Sets I to 0.
B = Nothing   ' Sets B to False.
```

If the variable is of a reference type — that is, an object variable — **Nothing** means the variable is not associated with any object. For example:

```
Dim MyObject As Object
MyObject = Nothing   ' No object currently referred to.
```

When you assign **Nothing** to an object variable, it no longer refers to any object instance. If the variable had previously referred to an instance, setting it to **Nothing** does not terminate the instance itself. The instance is terminated, and the memory and system resources associated with it are released, only after the garbage collector detects there are no active references remaining.

Object Lifetime: How Objects are Created and Destroyed | Dim Statement | Lifetime

NotInheritable

The **NotInheritable** keyword specifies that a class cannot be used as a base class.

The **NotInheritable** keyword is used in this context:

Class Statement

See Also

Visual Basic Language Keywords

NotOverridable

The **NotOverridable** keyword specifies that a property or procedure cannot be overridden in a derived class.

The **NotOverridable** keyword is used in these contexts:

Function Statement

Property Statement

Sub Statement

See Also

Visual Basic Language Keywords | Shadowing

Off

The **Off** keyword turns a compiler option off.

The **Off** keyword is used in these contexts:

Option Explicit Statement

Option Strict Statement

See Also

Visual Basic Language Keywords

On

The **On** keyword either introduces a response to a run-time error or turns a compiler option on.

The **On** keyword is used in these contexts:

On Error Statement

Option Explicit Statement

Option Strict Statement

See Also

Visual Basic Language Keywords

Option

The **Option** keyword is used in these contexts:

Option Compare Statement

Option Explicit Statement

Option Strict Statement

See Also

Visual Basic Language Keywords

Optional

The **Optional** keyword indicates that a procedure argument can be omitted when the procedure is called.

The **Optional** keyword is used in these contexts:

Declare Statement

Function Statement

Property Statement

Sub Statement

See Also

Visual Basic Language Keywords

Overloads

The **Overloads** keyword declares a property or method with the same name as an existing member, but with an argument list different from the original member.

Overloads can also be used to shadow an existing member, or set of overloaded members, in a base class. When you use **Overloads** in this way, you declare the property or method with the same name and the same argument list as the base class member, and you do not supply the **Shadows** keyword.

The **Overloads** keyword is used in these contexts:

Function Statement

Property Statement

Sub Statement

See Also

Shadows | Procedure Overloading

Overridable

The **Overridable** keyword specifies that a property or method can be overridden in a derived class.

The **Overridable** keyword is used in these contexts:

Function Statement

Property Statement

Sub Statement

See Also

Visual Basic Language Keywords | Shadowing

Overrides

The **Overrides** keyword specifies that a property or method overrides a member inherited from a base class.

The **Overrides** keyword is used in these contexts:

Function Statement

Property Statement

Sub Statement

See Also

Visual Basic Language Keywords | Shadowing

P-Z Keywords

The following table contains a listing of the Visual Basic .NET language keywords.

ParamArray	Preserve	Private	Protected
Public	ReadOnly	Resume	Shadows
Shared	Static	Step	Then
To	True	TypeOf	Unicode
Until	When	While	WithEvents
WriteOnly			

See Also

A–E Keywords | F–O Keywords | Visual Basic Language and Run-Time Reference

ParamArray

The **ParamArray** keyword indicates that a procedure argument is an optional array of elements of the specified type. **ParamArray** can be used only on the last argument of an argument list. It allows you to pass an arbitrary number of arguments to the procedure. A **ParamArray** argument is always passed using **ByVal**.

The **ParamArray** keyword is used in these contexts:

Declare Statement

Function Statement

Property Statement

Sub Statement

See Also

Visual Basic Language Keywords | Parameter Arrays

Preserve

The **Preserve** keyword prevents the contents of an array from being cleared when the array is redimensioned.

The **Preserve** keyword is used in this context:

ReDim Statement

See Also

Visual Basic Language Keywords

Private

The **Private** keyword confers private access on one or more declared programming elements. Private elements are accessible only from within their declaration context, including from members of any nested types, for example from within a nested procedure or from an assignment expression in a nested enumeration.

The **Private** keyword is used in these contexts:

Class Statement

Const Statement

Declare Statement

Delegate Statement

Dim Statement

Enum Statement

Event Statement

Function Statement

Interface Statement

Property Statement

Structure Statement

Sub Statement

See Also

Accessibility | Procedures | Structures: Your Own Data Types | Understanding Classes

Protected

The **Protected** keyword confers protected access on one or more declared programming elements. Protected elements are accessible only from within their own class or from a derived class. Protected access is not a superset of friend access.

The **Protected** keyword can be used in conjunction with the **Friend** keyword in the same declaration. This combination confers both friend and protected access on the declared elements, so they are accessible from the same assembly, from their own class, and from any derived classes.

The **Protected** keyword is used in these contexts:

Class Statement

Const Statement

Declare Statement

Delegate Statement

Dim Statement

Enum Statement

Event Statement

Function Statement

Interface Statement

Property Statement

Structure Statement

Sub Statement

See Also

Friend | Accessibility | Procedures | Structures: Your Own Data Types | Understanding Classes

Public

The **Public** keyword confers public access on one or more declared programming elements. There are no restrictions on the accessibility of public elements.

The **Public** keyword is used in these contexts:

Class Statement

Const Statement

Declare Statement

Delegate Statement

Dim Statement

Enum Statement

Event Statement

Function Statement

Interface Statement

Module Statement

Property Statement

Structure Statement

Sub Statement

See Also

Accessibility | Procedures | Structures: Your Own Data Types | Understanding Classes

ReadOnly

The **ReadOnly** keyword indicates that a variable or property can be read but not written.

The **ReadOnly** keyword is used in these contexts:

Dim Statement

Property Statement

See Also

Visual Basic Language Keywords

Resume

The **Resume** keyword indicates where execution should continue after an error has been handled.

The **Resume** keyword is used in these contexts:

On Error Statement

Resume Statement

See Also

Visual Basic Language Keywords | Exception Handling

Shadows

The **Shadows** keyword indicates that a declared programming element shadows, or hides, an identically named element, or set of overloaded elements, in a base class. You can shadow any kind of declared element with any other kind.

A shadowed element is normally unavailable from within the derived class that shadows it. However, the following considerations apply:

- If the shadowing element is not accessible from the code referring to it, for example if it is **Private**, the reference is resolved to the shadowed element.
- If you shadow an element, you can still access the shadowed element through an object declared with the type of the base class.

The purpose of shadowing is to protect the definition of your class members. The base class might undergo a change that creates an element with the same name as one you have already defined. If this happens, the **Shadows** keyword forces references through your class to be resolved to your previously defined member, instead of to the new base class element.

The **Shadows** keyword is used in these contexts:

Class Statement

Const Statement

Declare Statement

Delegate Statement

Dim Statement

Enum Statement

Event Statement

Function Statement

Interface Statement

Property Statement

Structure Statement

Sub Statement

See Also

Shadowing | Private | Protected

Shared

The **Shared** keyword indicates that one or more declared programming elements are shared. Shared elements are not associated with a specific instance of a class or structure. You can access them by qualifying them either with the class or structure name, or with the variable name of a specific instance of the class or structure.

The **Shared** keyword is used in these contexts:

Dim Statement

Event Statement

Function Statement

Property Statement

Sub Statement

See Also

Lifetime | Procedures | Structures: Your Own Data Types | Understanding Classes

Static

The **Static** keyword indicates that one or more declared variables are static. Static variables remain in existence and retain their latest values after termination of the procedure in which they are declared.

The **Static** keyword is used in this context:

Dim Statement

See Also

Lifetime | Variable Declaration | Structures: Your Own Data Types | Understanding Classes

Step

The **Step** keyword specifies an increment value for a loop counter.

The **Step** keyword is used in this context:

For...Next Statements

See Also

Visual Basic Language Keywords

Then

The **Then** keyword introduces a statement block to be compiled or executed if a tested condition is true.

The **Then** keyword is used in these contexts:

#If...Then...#Else Directives

If...Then...Else Statements

See Also

Visual Basic Language Keywords

To

The **To** keyword separates the beginning and ending values of a loop counter or of a value match range.

The **To** keyword is used in these contexts:

For...Next Statements

Select...Case Statements

See Also

Visual Basic Language Keywords

True

The **True** keyword represents a Boolean value that passes a conditional test.

See Also

Boolean Data Type | False

TypeOf

The **TypeOf** keyword introduces a comparison clause that tests whether an object is derived from or implements a particular type, such as an interface.

The **TypeOf** keyword is used in this context:

If...Then...Else Statements

See Also

Comparison Operators | Object Variable Values | Determining Object Type

Unicode

The **Unicode** keyword indicates that strings are converted to Unicode values regardless of the name of the method being declared.

The **Unicode** keyword is used in this context:

Declare Statement

Smart Device Developer Notes

This keyword is not supported.

See Also

Visual Basic Language Keywords

Until

The **Until** keyword specifies a condition that terminates the execution of a **Do** loop.

The **Until** keyword is used in this context:

Do...Loop Statements

See Also

Visual Basic Language Keywords

When

The **When** keyword adds a conditional test to a **Catch** statement.

The **When** keyword is used in this context:

Try...Catch...Finally Statements

See Also

Visual Basic Language Keywords

While

The **While** keyword specifies a condition that allows the execution of a **Do** loop to continue. The **While** keyword is not the same as the opening statement of the **While...End While** block.

The **While** keyword is used in this context:

Do...Loop Statements

See Also

While...End While Statements

WithEvents

The **WithEvents** keyword indicates that a declared object variable refers to a class instance that can raise events.

The **WithEvents** keyword is used in this context:

Dim Statement

See Also

Visual Basic Language Keywords | Events and Delegates | WithEvents and the Handles Clause

WriteOnly

The **WriteOnly** keyword indicates that a property can be written but not read.

The **WriteOnly** keyword is used in this context:

Property Statement

Add Method

Clear Method

Raise Method

Remove Method

Related Sections

Visual Basic Language and Run-Time Reference

Visual Basic Language

Add Method

Adds a member to a **Collection** object.

```
Public Sub Add( _
   ByVal Item As Object, _
   Optional ByVal Key As String, _
   Optional ByVal { Before | After } As Object = Nothing _
)
```

Parameters

Item
Required. An object of any type that specifies the member to add to the collection.

Key
Optional. A unique **String** expression that specifies a key string that can be used instead of a positional index to access a member of the collection.

Before
Optional. An expression that specifies a relative position in the collection. The member to be added is placed in the collection before the member identified by the *Before* argument. If *Before* is a numeric expression, it must be a number from 1 to the value of the collection's **Count** property. If *Before* is a **String** expression, it must correspond to the key string specified when the member being referred to was added to the collection. You cannot specify both *Before* and *After*.

After
Optional. An expression that specifies a relative position in the collection. The member to be added is placed in the collection after the member identified by the *After* argument. If *After* is a numeric expression, it must be a number from 1 to the value of the collection's **Count** property. If *After* is a **String** expression, it must correspond to the key string specified when the member referred to was added to the collection. You cannot specify both *Before* and *After*.

Exceptions/Error Codes

Exception type	Error number	Condition
ArgumentException	5	Both *Before* and *After* are specified, or argument does not refer to an existing member of the collection.
ArgumentException	5	The specified *Key* already exists.

Remarks

The *Before* or *After* argument must refer to an existing member of the collection; otherwise, an error occurs.

An error also occurs if a specified *Key* value matches the key for an existing member of the collection.

Example

This example uses the **Add** method to add `Child` objects — instances of a class called `Child` containing a **Public** property `Name` — to a collection called `Family`. To see how this works, create a **Form** with two **Buttons** and set their **Text** properties to Add and List. Add the **Child** class definition and the **Family** declaration to the form code. Modify the **Click** events for the **Add** and **List** buttons as shown. The **Add** button allows you to add children. The **List** button will display the names of all the children.

```
Public Class Child
   Public Name As String
   Sub New(ByVal newName As String)
      Name = newName
   End Sub
End Class

Private family As New Collection() ' Create a Collection object.

Private Sub AddChild_Click(ByVal sender As System.Object, _
ByVal e As System.EventArgs) Handles Button1.Click
   Dim newName As String
```

```
    newName = InputBox("Name of new family member: ")
    If newName <> "" Then
       family.Add(New Child(newName), newName)
    End If
End Sub

Private Sub ListChild_Click(ByVal sender As System.Object, _
ByVal e As System.EventArgs) Handles Button2.Click
    Dim aChild As Child
    For Each aChild In family
       MsgBox(aChild.Name)
    Next
End Sub
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Collection

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Item Property | Remove Method | ArgumentException Class

Applies To

Collection Object

Clear Method

Clears all property settings of the **Err** object.

```
object.Clear
```

Parameter

object

Always the **Err** object.

Remarks

Use **Clear** to explicitly clear the **Err** object after an error has been handled, such as when you use deferred error handling with **On Error Resume Next**. The **Clear** method is called automatically whenever any of the following statements executes:

- Any type of **Resume** statement
- **Exit Sub**, **Exit Function**, or **Exit Property**
- Any **On Error** statement
- Any **Try...Catch...Finally** statement

> **Note** The **On Error Resume Next** construct may be preferable to **On Error GoTo** when handling errors generated during access to other objects. Checking **Err** after each interaction with an object removes ambiguity about which object was accessed by the code: you can be sure which object placed the error code in **Err.Number**, as well as which object originally generated the error (the object specified in **Err.Source**).

Example

This example uses the **Err** object's **Clear** method to reset the numeric properties of the **Err** object to zero and its string properties to zero-length strings. Without the call to **Clear**, the second call to **MsgBox** would display the same error message.

```
Sub ClearErr()
   ' Produce overflow error
   On Error Resume Next
   Dim zero As Integer = 0
   Dim result As Integer = 8 / zero
   MsgBox(Err.Description)
   Err.Clear()
   MsgBox(Err.Description)
End Sub
```

Requirements

Namespace: Microsoft.VisualBasic

Class: Err Object

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Description Property | Err Object | HelpContext Property | HelpFile Property | LastDLLError Property | Number Property | On Error Statement | Raise Method | Source Property

Applies To

Err Object

GetEnumerator Method

Returns a reference to an **IEnumerator** interface, whose purpose is to grant access to an enumeration's items.

```
Public Function GetEnumerator() As IEnumerator
```

Remarks

When **GetEnumerator** is called, it constructs an enumerator object containing the current version number in the collection and a reference to the collection's items. Every time the enumerator is accessed, it compares the version of the enumerator with the version of the collection. If the versions do not match, it means that the collection has changed; an exception then occurs.

Example

The following example shows how to use **GetEnumerator** to retrieve a member of an enumeration.

```
Imports System.Collections
Public Class TestClass : Implements IEnumerable

Public Function GetEnumerator() As IEnumerator Implements _
IEnumerable.GetEnumerator
   Return CType(Me, IEnumerator)
End Function
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Collection

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

IEnumerator Interface

Applies To

Collection Object

Raise Method

Generates a run-time error; can be used instead of the **Error** statement.

```
Public Sub Raise( _
   ByVal Number As Integer, _
   Optional ByVal Source As Object = Nothing, _
   Optional ByVal Description As Object = Nothing, _
   Optional ByVal HelpFile As Object = Nothing, _
   Optional ByVal HelpContext As Object = Nothing _
)
```

Parameter

Number
Required. **Long** integer that identifies the nature of the error. Visual Basic errors are in the range 0–65535: the range 0–512 is reserved for system errors; the range 513–65535 is available for user-defined errors. When setting the **Number** property to your own error code in a class module, you add your error code number to the **vbObjectError** constant. For example, to generate the error number 513, assign `vbObjectError + 513` to the **Number** property.

Source
Optional. **String** expression naming the object or application that generated the error. When setting this property for an object, use the form *project.class*. If *Source* is not specified, the process ID of the current Visual Basic project is used.

Description
Optional. **String** expression describing the error. If unspecified, the value in the **Number** property is examined. If it can be mapped to a Visual Basic run-time error code, the string that would be returned by the **Error** function is used as the **Description** property. If there is no Visual Basic error corresponding to the **Number** property, the "Application-defined or object-defined error" message is used.

HelpFile
Optional. The fully qualified path to the Help file in which help on this error can be found. If unspecified, Visual Basic uses the fully qualified drive, path, and file name of the Visual Basic Help file.

HelpContext
Optional. The context ID identifying a topic within *HelpFile* that provides help for the error. If omitted, the Visual Basic Help file context ID for the error corresponding to the **Number** property is used, if it exists.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Number* is greater than 65535 .

Remarks

All of the **Raise** arguments except *Number* are optional. If you omit optional arguments, and the property settings of the **Err** object contain values that have not been cleared, those values serve as the values for your error.

Raise is useful for generating errors when writing class modules, because the **Err** object gives richer information than when you generate errors with the **Error** statement. For example, with the **Raise** method, the source that generated the error can be specified in the **Source** property, online Help for the error can be referenced, and so on.

Example

This example uses the **Err** object's **Raise** method to generate an error within a function written in Visual Basic. The calling function can catch the error and report it to the user with a message box.

```
Const WidthError = 1
Const WidthHelp = 101

Function TestWidth(ByVal width As Integer)
   If width > 1000 Then
      Err.Raise(vbObjectError + 512 + WidthError, "TestWidth", _
      "Width must be less than 1000.", "HelpFile.hlp", WidthHelp)
```

```
    End If
End Function

' Add to calling function.
Try
    TestWidth(2000)
Catch ex As Exception
    MsgBox(ex.Message)
End Try
```

Requirements

Namespace: Microsoft.VisualBasic

Class: Err Object

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Remove Method

Removes a member from a **Collection** object.

```
Public Overloads Sub Remove(ByVal { Key As String | Index As Integer })
```

Parameters

Key
A unique **String** expression that specifies a key string that can be used, instead of a positional index, to access a member of the collection.

Index
An expression that specifies the position of a member of the collection. If a numeric expression, *Index* must be a number from 1 to the value of the collection's **Count** property. If a **String** expression, *Index* must correspond to the *Key* argument specified when the member referred to was added to the collection.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	*Key* is invalid or not specified.
IndexOutOfRangeException	9	*Index* does not match an existing member of the collection.

Remarks

If *Index* doesn't match an existing member of the collection, an error occurs.

Example

This example illustrates the use of the **Remove** method to remove objects from a **Collection** object, `birthdays`.

```
Dim birthdays As New Collection()
birthdays.Add(New DateTime(2001, 1, 12), "Bill")
birthdays.Add(New DateTime(2001, 1, 13), "Joe")
birthdays.Remove(1)
birthdays.Remove("Joe")
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Collection

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Visual Basic Language

Collection Object

A **Collection** object is an ordered set of items that can be referred to as a unit.

Remarks

The **Collection** object provides a convenient way to refer to a related group of items as a single object. The items, or members, in a collection need only be related by the fact that they exist in the collection. Members of a collection do not have to share the same data type.

You can create a collection the same way you create other objects. For example:

```
Dim X As New Collection
```

Once you have created a collection, you can add members with the **Add** method and remove them with the **Remove** method. You can return specific members from the collection with the **Item** method, and iterate through the entire collection with the **For Each...Next** statement.

> **Note** Although the **Collection** object in version 6 and in .NET have identical functionality, they cannot interoperate in a COM environment.
>
> **Caution** Enumerating through a collection is not a thread-safe procedure. Even if the collection is synchronized, other threads can still modify the collection, causing the enumerator to throw an exception. To guarantee thread safety during enumeration, either lock the collection or catch the exceptions resulting from changes made by other threads.

Example

This example creates a **Collection** object (`MyClasses`), and then creates a dialog box in which users can add objects to the collection. To see how this works, choose the **Class** command from the **Project** menu and declare a public variable called `InstanceName` at module level of `Class1` (type `Public InstanceName`) to hold the names of each instance. Leave the default name as `Class1`. Copy and paste the following code into the General section of another module, and then start it with the statement `ClassNamer` in another procedure. (This example only works with host applications that support classes.)

```
Public Class Class1
   Public InstanceName As String
End Class

Sub ClassNamer()
   Dim MyClasses As New Collection()   ' Create a Collection object.
   Dim number As Integer   ' Counter for individualizing keys.
   Dim Msg As String   ' Variable to hold prompt string.
   Dim name As String
   Dim oneInst As Class1
   Dim nameList As String = ""
   Do
      Dim inst As New Class1()   ' Create a new instance of Class1.
      number += 1   ' Increment Num, then get a name.
      Msg = "Please enter a name for this object." & ControlChars.CrLf _
         & "Press Cancel to see names in collection."
      name = InputBox(Msg, "Name the Collection Items")
      Inst.InstanceName = name   ' Put name in object instance.
      ' If user entered name, add it to the collection.
      If inst.InstanceName <> "" Then
         ' Add the named object to the collection.
         MyClasses.Add (inst, number.ToString())
      End If
   Loop Until name = ""

   For Each oneInst In MyClasses   ' Create list of names.
      nameList &= oneInst.InstanceName & ControlChars.CrLf
   Next

   ' Display the list of names in a message box.
   MsgBox (nameList, , "Instance Names In MyClasses Collection")
```

```
    Dim count As Integer
    For count = 1 To MyClasses.Count
       ' Remove name from the collection.
       MyClasses.Remove(1)
       ' Since collections are reindexed automatically, remove
       ' the first member on each iteration
    Next
End Sub
```

Collection Object Properties and Methods

Properties

Count Property	Read-only. Returns an integer containing the number of objects in a collection.
Item Property	Returns a specific member of a **Collection** object either by position or by key.

Methods

Add Method	Adds a member to a **Collection** object.
GetEnumerator Method	Returns a reference to an **IEnumerator** interface, whose purpose is to grant access to an enumeration's items.
Remove Method	Removes a member from a **Collection** object.

See Also

Collection Object

Err Object

Contains information about run-time errors.

Remarks

The properties of the **Err** object are set by the generator of an error — Visual Basic, an object, or the programmer.

When a run-time error occurs, the properties of the **Err** object are filled with information that uniquely identifies the error, and information you can use to handle it. To generate a run-time error in your code, use the **Raise** method.

The **Err** object's properties are reset to zero or zero-length strings ("") after an **Exit Sub**, **Exit Function**, **Exit Property**, or **Resume Next** statement within an error-handling routine. Using any form of the **Resume** statement outside of an error-handling routine will not reset the **Err** object's properties. You can use the **Clear** method to explicitly reset **Err**.

Use the **Raise** method rather than the **Error** statement to generate run-time errors for system errors and class modules. Whether you use the **Raise** method in other code depends on the richness of the information you want to return.

The **Err** object is an intrinsic object with global scope. Therefore, you do not need to create an instance of it in your code.

Example

This example uses the properties of the **Err** object in constructing an error-message dialog box. Note that if you use the **Clear** method first, when you generate a Visual Basic error with the **Raise** method, Visual Basic's default values become the properties of the **Err** object.

```
Dim Msg As String
' If an error occurs, construct an error message.
On Error Resume Next   ' Defer error handling.
Err.Clear
Err.Raise(6)   ' Generate an "Overflow" error.
' Check for error, then show message.
If Err.Number <> 0 Then
   Msg = "Error # " & Str(Err.Number) & " was generated by " _
      & Err.Source & ControlChars.CrLf & Err.Description
   MsgBox(Msg, MsgBoxStyle.Information, "Error")
End If
```

Requirements

Namespace: **Microsoft.VisualBasic**

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Err Object Properties and Methods

Properties

Description Property	Read/write. Returns or sets a descriptive string associated with a n error.
Erl Property	Read-only. Returns an integer indicating the line number of the l ast executed statement.
HelpContext Property	Read/write. Returns or sets an **Integer** containing the context ID for a topic in a Help file.
HelpFile Property	Read/write. Returns or sets a **String** expression containing the f ully qualified path to a Help file.
LastDLLError Property	Read-only. Returns a system error code produced by a call to a dynamic-link library (DLL).
Number Property	Read/write. Returns or sets a numeric value specifying an error.
Source Property	Read/write. Returns or sets a **String** expression specifying the n ame of the object or application that originally generated the err or.

Methods

Clear Method	Clears all property settings of the **Err** object.
Raise Method	Generates a run-time error; can be used instead of the **Error** stat ement.

Operator Precedence in Visual Basic

When several operations occur in an expression, each part is evaluated and resolved in a predetermined order called *operator precedence*.

When expressions contain operators from more than one category, they are evaluated according to the following rules:

- The arithmetic and concatenation operators have the order of precedence described below, and all have higher precedence than the comparison, logical, and bitwise operators.
- Comparison operators have equal precedence, and all have higher precedence than the logical and bitwise operators, but lower precedence than the arithmetic and concatenation operators.
- Logical and bitwise operators have the order of precedence described below, and all have lower precedence than the arithmetic, concatenation, and comparison operators.
- Operators with equal precedence are evaluated left to right in the order in which they appear in the expression.

Operators are evaluated in the following order of precedence:

Arithmetic and Concatenation Operators

Exponentiation (**^**)

Unary negation (**–**)

Multiplication and division (*****, **/**)

Integer division (****)

Modulus arithmetic (**Mod**)

Addition and subtraction (**+**, **–**), string concatenation (**+**)

String concatenation (**&**)

Arithmetic bit shift (**<<**, **>>**)

Comparison Operators

All comparison operators (**=**, **<>**, **<**, **<=**, **>**, **>=**, **Like**, **Is**, **TypeOf...Is**)

Logical and Bitwise Operators

Negation (**Not**)

Conjunction (**And**, **AndAlso**)

Disjunction (**Or**, **OrElse**, **Xor**)

The string concatenation operator (**&**) is not an arithmetic operator, but in precedence it is grouped with the arithmetic operators.

The **Is** operator is an object reference comparison operator. It does not compare objects or their values; it checks only to determine if two object variables refer to the same object.

When operators of equal precedence occur together in an expression, for example multiplication and division, each operation is evaluated as it occurs from left to right. Parentheses can be used to override the order of precedence and to force some parts of an expression to be evaluated before others. Operations within parentheses are always performed before those outside. Within parentheses, however, operator precedence is maintained. The following example illustrates this:

```
Dim A, B, C, D, E, F, G As Double
A = 3.0
B = 6.0
C = 4.0
D = 2.0
E = 1.0
F = A + B - C / D * E
' The previous line sets F to 7.0. Because of natural operator
' precedence, it is exactly equivalent to the following line:
F = (A + B) - ((C / D) * E)
```

```
' The following line overrides the natural operator precedence:
G = A + (B - C) / (D * E)
' The previous line sets G to 4.0.
```

Operators | Operator Precedence in Visual Basic

& Operator

Generates a string concatenation of two expressions.

```
result = expression1 & expression2
```

Parts

result
Required. Any **String** or **Object** variable.
expression1
Required. Any expression with a data type that widens to **String**.
expression2
Required. Any expression with a data type that widens to **String**.

Remarks

If the data type of *expression1* or *expression2* is not **String** but widens to **String**, it is converted to **String**. If one of the data types does not widen to **String**, the compiler generates an error.

The data type of *result* is **String**. If one or both expressions are stated as Nothing or have a value of **DBNull.value**, they are treated as a string with a value of "".

Example

This example uses the **&** operator to force string concatenation. The result is a string value representing the concatenation of the two string operands.

```
Dim myStr As String
myStr = "Hello" & " World"   ' Returns "Hello World".
```

See Also

&= Operator | Concatenation Operators | Operator Precedence in Visual Basic | Operators Listed by Functionality | Concatenation Operators

* Operator

Multiplies two numbers.

```
number1 * number2
```

Parts

number1
Required. Any numeric expression.
number2
Required. Any numeric expression.

Result

The result is the product of *number1* and *number2*

Supported Types

Byte, **Short**, **Integer**, **Long**, **Single**, **Double**, **Decimal**

Remarks

The data type of the result is the same as that of the data type with the greatest range. The order of range, from least to greatest range, is Byte, Short, Integer, Long, Single, Double, and Decimal.

If an expression is stated as Nothing, or is Empty, it is treated as zero.

Example

This example uses the ***** operator to multiply two numbers. The result is the product of the two operands.

```
Dim myValue As Double
myValue = 2 * 2   ' Returns 4.
myValue = 459.35 * 334.90   ' Returns 153836.315.
```

See Also

*= Operator | Arithmetic Operators | Operator Precedence in Visual Basic | Operators Listed by Functionality | Arithmetic Operators

*= Operator

Multiplies the value of a variable by the value of an expression and assigns the result to the variable.

```
variable *= expression
```

Parts

variable
Required. Any numeric variable.
expression
Required. Any numeric expression.

Example

The following example uses the ***=** operator to multiply one **Integer** variable by a second and assign the result to the first variable.

```
Dim var1 As Integer = 10
Dim var2 As Integer = 3
var1 *= var2   ' The value of var1 is now 30.
```

See Also

&= Operator | * Operator | += Operator | -= Operator | /= Operator | = Operator | \= Operator | ^= Operator | Assignment Operators | Arithmetic Operators | Operator Precedence in Visual Basic | Operators Listed by Functionality | Assignment Statements

+ Operator

Adds two numbers. Also used to concatenate two strings.

```
expression1 + expression2
```

Parts

expression1
Required. Any numeric expression or string.
expression2
Required. Any numeric expression or string.

Result

The value of the result will be the sum of *expression1* and *expression2* if *expression1* and *expression2* are numeric or the result of the concatenation of *expression1* and *expression2* if *expression1* and *expression2* are strings.

Supported Types

Byte, **Short**, **Integer**, **Long**, **Single**, **Double**, **Decimal**, **String**.

Remarks

When you use the **+** operator, you may not be able to determine whether addition or string concatenation will occur. Use the **&** operator for concatenation to eliminate ambiguity and provide self-documenting code.

If neither expression is an **Object**, the following rules apply:

If	**Then**
Both expressions are the same numeric data types (**Byte**, **Short**, **Integer**, **Long**, **Single**, **Double**, or **Decimal**)	Add.
Both expressions are strings	Concatenate.
One expression is a numeric data type and the other is a string	If **Option Strict** is **On**, a compile error is generated; if **Option Strict** is **Off**, implicitly convert **String** to **Double** and add. If **String** cannot be converted to a numeric value, an **InvalidCastException** is thrown.
One expression is a numeric data type, and the other is **Nothing**	If **Option Strict** is **On** a compile error is generated; if **Option Strict** is **Off**, add, with **Nothing** valued at zero.
One expression is a string, and the other is **Nothing**	If **Option Strict** is **On** a compile error is generated; if **Option Strict** is **Off**, concatenation, with **Nothing** = "".

If one expression is an **Object** expression, the following rules apply.

If	**Then**
One expression is a numeric **Object** expression and the other is a numeric value type	If **Option Strict** is **On**, a compiler error is generated; if **Option Strict** is **Off,** add.
One expression is a numeric **Object** expression and the other is a **String** type	If **Option Strict** is **On**, a compiler error is generated; if **Option Strict** is **Off**, implicitly convert **String** to **Double** and add. If **String** cannot be converted to a numeric value, an **InvalidCastException** is thrown.
One expression is a string **Object** expression and the other is a **String** type	If **Option Strict** is **On**, a compiler error is generated; if **Option Strict** is **Off**, implicitly convert **Object** to **String,** and then concatenate.
One expression is a string **Object** expression and the other is a numeric value type	If **Option Strict** is **On**, a compiler error is generated; if **Option Strict** is **Off**, implicitly convert **Object** to **Double** and add. If **Object** cannot be converted to a numeric value, an **InvalidCastException** is thrown.

If both expressions are **Object** expressions, the following rules apply (**Option Strict Off** only):

If	Then
Both **Object** expressions are numeric	Add.
Both **Object** expressions are strings	Concatenate.
One **Object** expression is numeric and the other is a string	Implicitly cast the numeric **Object** to **Double** and add. If **Object** cannot be converted to a numeric value, an **InvalidCastException** is thrown.

If one or both expressions are stated as Nothing or have a value of **DBNull**, they are treated as a string with a value of "".

Example

This example uses the **+** operator to add numbers. You can also use the **+** operator to concatenate strings. However, to eliminate ambiguity, you should use the **&** operator instead. If the components of an expression created with the **+** operator are numeric, the arithmetic result is assigned. If the components are exclusively strings, the strings are concatenated. The expression cannot contain components of mixed types. The arithmetic result returns the sum of the two operands. The concatenation result returns a string representing the concatenation of the two operands.

```
Dim myNumber As Integer
Dim var1 As String
Dim var2 As Integer
myNumber = 2 + 2   ' Returns 4.
myNumber = 4257.04 + 98112   ' Returns 102369.04.

Option Strict On
' Initialize mixed variables.
var1 = "34"
var2 = 6
myNumber = var1 + var2   ' Generates a compile-time error.

Option Strict Off
Var1 = "34"
Var2 = 6
myNumber = var1 + var2
' Returns 40 (addition) after the string in var1 is
' converted to a numeric value. Use of Option Strict Off
' for these operations is not recommended.
```

See Also

& Operator | Concatenation Operators | Arithmetic Operators | Operators Listed by Functionality | Operator Precedence in Visual Basic | Arithmetic Operators (Conceptual)

+= Operator

Adds the value of an expression to the value of a variable and assigns the result to the variable. Also concatenates a **String** expression to a **String** variable and assigns the result to the variable.

```
variable += expression
```

Parts

variable
Required. Any numeric or **String** variable.
expression
Required. Any numeric or **String** expression.

Remarks

This statement will implicitly perform widening but not narrowing conversions if the compilation environment is enforcing strict semantics. For details on these conversions, see Widening and Narrowing Conversions. If permissive semantics are allowed, the operator will implicitly perform a variety of string and numeric conversions. These conversions are identical to the conversions described for the **+** operator. For details on how these conversions are performed, see + Operator. For more information on strict and permissive semantics, see Option Strict Statement.

Example

These examples use the **+=** operator to combine the value of one variable with another. In the first example, **+=** is used with numeric variables to add one value to another. In the second example, **+=** is used with **String** variables to concatenate one value with another. In both cases, the result is assigned to the first variable.

```
Dim var1 As Integer = 10
Dim var2 As Integer = 3
var1 += var2   ' The value of var1 is now 13.

' This example uses string variables.
Dim var1 As String = "10"
Dim var2 As String = "3"
var1 += var2   ' The value of var1 is now "103".
```

See Also

+ Operator | -= Operator | Assignment Operators | Arithmetic Operators | Concatenation Operators | Operator Precedence in Visual Basic | Operators Listed by Functionality | Assignment Statements

= Operator

Used to assign a value to a variable or property.

```
variable = value
```

Parts

variable
Any variable or any writable property.
value
Any literal, constant, or expression.

Remarks

The name on the left side of the equal sign can be a simple scalar variable, a property, or an element of an array. Properties on the left side of the equal sign can only be those properties that are writable at run time. When used, the value on the right side of the equation is assigned to the variable on the left side of the equation.

Example

This example demonstrates use of the assignment operator. The value on the right side of the expression is assigned to the variable on the left side of the expression.

```
Dim myInt as Integer
Dim myString as String
Dim myButton as System.Windows.Forms.Button
Dim myObject as Object
myInt = 42
myString = "This is an example of a string literal"
myButton = New System.Windows.Forms.Button()
myObject = myInt
myObject = myString
myObject = myButton
```

See Also

&= Operator | *= Operator | += Operator | -= Operator | /= Operator | \= Operator | ^= Operator | Assignment Statements

- Operator

Yields the difference between two numbers or indicates the negative value of a numeric expression.

Syntax 1

```
expression1 - expression2
```

Syntax 2

```
-number
```

Parts

number
Required. Any numeric expression.
number1
Required. Any numeric expression.
number2
Required. Any numeric expression.

Result

The result will be the difference between *number1* and *number2*.

Supported Types

Byte, **Short**, **Integer**, **Long**, **Single**, **Double**, **Decimal**

Remarks

In Syntax 1, the **–** operator is the arithmetic subtraction operator for the difference between two numbers. In Syntax 2, the **–** operator is the unary negation operator for the negative value of an expression. The data type of the result is the same as that of the data type with the greatest range. The order of range, from least to greatest range, is Byte, Short, Integer, Long, Single, Double, and Decimal.

If an expression is stated as Nothing, it is treated as zero.

Example

This example uses the **-** operator to calculate and return the difference between two numbers.

```
Dim myResult As Double
myResult = 4 - 2   ' Returns 2.
myResult = 459.35 - 334.90   ' Returns 124.45.
```

See Also

-= Operator | Arithmetic Operators | Operator Precedence in Visual Basic | Operators Listed by Functionality | Arithmetic Operators

-= Operator

Subtracts the value of an expression from the value of a variable and assigns the result to the variable.

```
variable -= expression
```

Parts

variable
Required. Any numeric variable.
expression
Required. Any numeric expression.

Example

The following example uses the **-=** operator to subtract one **Integer** variable from another and assign the result to the latter variable.

```
Dim var1 As Integer = 10
Dim var2 As Integer = 3
var1 -= var2   ' The value of var1 is now 7.
```

See Also

&= Operator | *= Operator | += Operator | - Operator | /= Operator | = Operator | \= Operator | ^= Operator | Assignment Operators | Arithmetic Operators | Operator Precedence in Visual Basic | Operators Listed by Functionality | Assignment Statements

<< Operator

Performs an arithmetic left shift on a bit pattern.

```
result = pattern << amount
```

Parts

result
Required. Integral numeric value. The result of shifting the bit pattern. The data type is the same as that of *pattern*.
pattern
Required. Integral numeric expression. The bit pattern to be shifted. The data type must be **Byte**, **Short**, **Integer**, or **Long**.
amount
Required. Numeric expression. The number of bits to shift the bit pattern. The data type must be **Integer** or widen to **Integer**.

Remarks

Arithmetic shifts are not circular, which means the bits shifted off one end of the result are not reintroduced at the other end. In an arithmetic left shift, the bits shifted beyond the range of the result data type are discarded, and the bit positions vacated on the right are set to zero.

To prevent shifting by more bits than the result can hold, Visual Basic masks the value of *amount* with a size mask corresponding to the data type of *pattern*. The binary AND of these values is used for the shift amount. The size masks are as follows:

Data type of *pattern*	Size mask (decimal)	Size mask (hexadecimal)
Byte	7	&H00000007
Short	15	&H0000000F
Integer	31	&H0000001F
Long	63	&H0000003F

If *amount* is zero, the value of *result* is identical to the value of *pattern*. If *amount* is negative, it is taken as an unsigned value and masked with the appropriate size mask.

Arithmetic shifts never generate overflow exceptions.

Example

This example uses the **<<** operator to perform arithmetic left shifts on integral values. The result always has the same data type as that of the expression being shifted.

```
Dim Pattern As Short = 192   ' Bit pattern is 0000 0000 1100 0000.
Dim Result1, Result2, Result3, Result4, Result5 As Short
Result1 = Pattern << 0      ' Result is 192 (0000 0000 1100 0000).
Result2 = Pattern << 4     ' Result is 3072 (0000 1100 0000 0000).
Result3 = Pattern << 9   ' Result is -32768 (1000 0000 0000 0000).
Result4 = Pattern << 17     ' Result is 384 (0000 0001 1000 0000).
Result5 = Pattern << -1   ' Result is 0 (shifted 15 places to left).
```

The shift amount for `Result4` is calculated as 17 AND 15, which equals 1.

See Also

Bit Shift Operators | Assignment Operators | <<= Operator | Operator Precedence in Visual Basic | Operators Listed by Functionality | Arithmetic Operators

<<= Operator

Performs an arithmetic left shift on the value of a variable and assigns the result back to the variable.

```
variable <<= amount
```

Parts

variable
Required. Variable of data type **Byte**, **Short**, **Integer**, or **Long**.
amount
Required. Numeric expression of a data type that widens to **Integer**.

Remarks

Arithmetic shifts are not circular, which means the bits shifted off one end of the result are not reintroduced at the other end. In an arithmetic left shift, the bits shifted beyond the range of the result data type are discarded, and the bit positions vacated on the right are set to zero.

Example

The following example uses the **<<=** operator to shift the bit pattern of an **Integer** variable left by the specified amount and assign the result to the variable.

```
Dim Var As Integer = 10   ' Variable containing bit pattern to shift.
Dim Shift As Integer = 3   ' Amount to shift bit pattern.
Var <<= Shift   ' The value of Var is now 80.
```

See Also

>> Operator

Performs an arithmetic right shift on a bit pattern.

```
result = pattern >> amount
```

Parts

result
Required. Integral numeric value. The result of shifting the bit pattern. The data type is the same as that of *pattern*.
pattern
Required. Integral numeric expression. The bit pattern to be shifted. The data type must be **Byte**, **Short**, **Integer**, or **Long**.
amount
Required. Numeric expression. The number of bits to shift the bit pattern. The data type must be **Integer** or widen to **Integer**.

Remarks

Arithmetic shifts are not circular, which means the bits shifted off one end of the result are not reintroduced at the other end. In an arithmetic right shift, the bits shifted beyond the rightmost bit position are discarded, and the leftmost (sign) bit is propagated into the bit positions vacated at the left. This means that if *pattern* has a negative value, the vacated positions are set to one; otherwise they are set to zero.

Note that data type **Byte** is considered unsigned, so there is no sign bit to propagate. If *pattern* is of type **Byte**, the vacated positions are always set to zero.

To prevent shifting by more bits than the result can hold, Visual Basic masks the value of *amount* with a size mask corresponding to the data type of *pattern*. The binary AND of these values is used for the shift amount. The size masks are as follows:

Data type of *pattern*	Size mask (decimal)	Size mask (hexadecimal)
Byte	7	&H00000007
Short	15	&H0000000F
Integer	31	&H0000001F
Long	63	&H0000003F

If *amount* is zero, the value of *result* is identical to the value of *pattern*. If *amount* is negative, it is taken as an unsigned value and masked with the appropriate size mask.

Arithmetic shifts never generate overflow exceptions.

Example

This example uses the **>>** operator to perform arithmetic right shifts on integral values. The result always has the same data type as that of the expression being shifted.

```
Dim Pattern As Short = 2560   ' Bit pattern is 0000 1010 0000 0000.
Dim Result1, Result2, Result3, Result4, Result5 As Short
Result1 = Pattern >> 0   ' Result is 2560 (0000 1010 0000 0000).
Result2 = Pattern >> 4    ' Result is 160 (0000 0000 1010 0000).
Result3 = Pattern >> 10     ' Result is 2 (0000 0000 0000 0010).
Result4 = Pattern >> 18   ' Result is 640 (0000 0010 1000 0000).
Result5 = Pattern >> -1   ' Result is 0 (shifted 15 places to right).
```

The shift amount for `Result4` is calculated as 18 AND 15, which equals 2.

```
Dim NegPattern As Short = -8192   ' Bit pattern is 1110 0000 0000 0000.
Dim NegResult1, NegResult2 As Short
NegResult1 = NegPattern >> 4   ' Result is -512 (1111 1110 0000 0000).
NegResult2 = NegPattern >> 13   ' Result is -1 (sign bit propagated).
```

See Also

Bit Shift Operators | Assignment Operators | >>= Operator | Operator Precedence in Visual Basic | Operators Listed by Functionality | Arithmetic Operators

>>= Operator

Performs an arithmetic right shift on the value of a variable and assigns the result back to the variable.

```
variable >>= amount
```

Parts

variable
Required. Variable of data type **Byte**, **Short**, **Integer**, or **Long**.
amount
Required. Numeric expression of a data type that widens to **Integer**.

Remarks

Arithmetic shifts are not circular, which means the bits shifted off one end of the result are not reintroduced at the other end. In an arithmetic right shift, the bits shifted beyond the rightmost bit position are discarded, and the leftmost bit is propagated into the bit positions vacated at the left. This means that if *variable* has a negative value, the vacated positions are set to one. If *variable* is positive, or if its data type is **Byte**, the vacated positions are set to zero.

Example

The following example uses the **>>=** operator to shift the bit pattern of an **Integer** variable right by the specified amount and assign the result to the variable.

```
Dim Var As Integer = 10   ' Variable containing bit pattern to shift.
Dim Shift As Integer = 2   ' Amount to shift bit pattern.
Var >>= Shift   ' The value of Var is now 2 (bit lost off right end).
```

See Also

>> Operator | Assignment Operators | Bit Shift Operators | Operator Precedence in Visual Basic | Operators Listed by Functionality | Assignment Statements

/ Operator

Divides two numbers and returns a floating-point result.

```
number1 / number2
```

Parts

result
Required. Any numeric variable.
number1
Required. Any numeric expression.
number2
Required. Any numeric expression.

Result

The result is the quotient of *number1* divided by *number2*.

Supported Types

Byte, **Short**, **Integer**, **Long**, **Single**, **Double**, **Decimal**

Remarks

The data type of *result* is usually **Double**. The following are exceptions to this rule:

If	**Then *result* is**
One expression is **Single** and the other is any data type except **Double**	**Single**.
Both expressions are **Decimal** data types	**Decimal**. If a **Decimal** expression is divided by 0, a **DividebyZero** exception is raised. This exception only occurs with a **Decimal** expression.

If an expression is stated as Nothing, or is Empty, it is treated as zero.

Example

This example uses the **/** operator to perform floating-point division. The result is the quotient of the two operands.

```
Dim MyValue As Double
MyValue = 10 / 4   ' Returns 2.5.
MyValue = 10 / 3   ' Returns 3.333333.
```

See Also

\= Operator | \ Operator | Arithmetic Operators | Operator Precedence in Visual Basic | Operators Listed by Functionality | Arithmetic Operators

/= Operator

Divides the value of a variable by the value of an expression and assigns the result to the variable.

```
variable /= expression
```

Parts

variable
Required. Any numeric variable.
expression
Required. Any numeric expression.

Remarks

This statement assigns a **Double** to the variable on the left hand side. If **Option Strict** is **On**, *variable* must be a **Double**. If **Option Strict** is **Off**, an implicit conversion will be made and the resultant value assigned to *variable*, with a possible error at run time. For more information, see Widening and Narrowing Conversions, and Option Strict Statement.

Example

The following example uses the **/=** operator to divide one **Integer** variable by a second and assign the quotient to the first variable.

```
Dim var1 As Integer = 12
Dim var2 As Integer = 3
var1 /= var2   ' The value of var1 is now 4.
```

See Also

&= Operator | *= Operator | += Operator | -= Operator | / Operator | = Operator | \= Operator | ^= Operator | Assignment Operators | Arithmetic Operators | Operator Precedence in Visual Basic | Operators Listed by Functionality | Assignment Statements

\ Operator

Divides two numbers and returns an integer result.

```
number1 \ number2
```

Parts

number1
Required. Any numeric expression of an integral type.
number2
Required. Any numeric expression of an integral type.

Supported Types

Byte, **Short**, **Integer**, or **Long**.

Result

The result is the integer quotient of *number1* and *number2*, dropping the remainder.

Remarks

Before division is performed, any floating-point numeric expressions are coerced to **Long** if **Option Strict** is **Off**. If **Option Strict** is **On**, a compiler error results.

The data type of the result is **Byte**, **Short**, **Integer**, or **Long**. Any fractional portion is truncated.

If any expression is stated as Nothing, it is treated as zero. Attempting to perform integer division by zero causes a **DivideByZeroExeception** to be thrown.

Example

This example uses the **** operator to perform integer division. The result is an integer representing the integer quotient of the two operands.

```
Dim myValue As Integer
myValue = 11 \ 4   ' Returns 2.
myValue = 9 \ 3   ' Returns 3.
myValue = 100 \ 3   ' Returns 33.
MyValue = 67 \ -3   ' Returns -22.
```

See Also

\= Operator | / Operator | Arithmetic Operators | Operator Precedence in Visual Basic | Operators Listed by Functionality | Arithmetic Operators

\= Operator

Divides the value of a variable by the value of an expression and assigns the integer result to the variable.

```
variable \= expression
```

Parts

variable
Required. Any numeric variable.
expression
Required. Any numeric expression.

Remarks

For further information on integer division, see \ Operator.

Example

The following example uses the **\=** operator to divide one **Integer** variable by a second and assign the integer result to the first variable.

```
Dim var1 As Integer = 10
Dim var2 As Integer = 3
var1 \= var2   ' The value of var1 is now 3.
```

See Also

&= Operator | *= Operator | += Operator | -= Operator | /= Operator | = Operator | \ Operator | ^= Operator | Assignment Operators | Arithmetic Operators | Operator Precedence in Visual Basic | Operators Listed by Functionality | Assignment Statements

^ Operator

Raises a number to the power of another number.

```
Number ^ exponent
```

Parts

number
Required. Any numeric expression.
exponent
Required. Any numeric expression.

Result

The result value will be *number* raised to the *exponent* power.

Supported Types

Double. All operands of a different type will be converted to **Double**.

Remarks

Number can be negative only if *exponent* is an integer value. When more than one exponentiation is performed in a single expression, the **^** operator is evaluated as it is encountered from left to right.

Usually, the data type of *result* is **Double**.

Example

This example uses the **^** operator to raise a number to the power of an exponent. The result is the first operand raised to the power of the second.

```
Dim myValue As Double
myValue = 2 ^ 2   ' Returns 4.
myValue = 3 ^ 3 ^ 3   ' Returns 19683.
myValue = (-5) ^ 3   ' Returns -125.
myValue = (-5) ^ 4   ' Returns 625.
```

See Also

^= Operator | Arithmetic Operators | Operator Precedence in Visual Basic | Operators Listed by Functionality | Arithmetic Operators

^= Operator

Raises the value of a variable to the power of an expression and assigns the result back to the variable.

```
variable ^= expression
```

Parts

variable
Required. Any numeric variable.
expression
Required. Any numeric expression.

Example

The following example uses the **^=** operator to raise the value of one **Integer** variable to the power of a second variable and assign the result to the first variable.

```
Dim var1 As Integer = 10
Dim var2 As Integer = 3
var1 ^= var2   ' The value of var1 is now 1000.
```

AddressOf Operator

Creates a procedure delegate instance that references the specific procedure.

```
AddressOf procedurename
```

The required *procedurename* specifies the procedure that will be referenced by the newly created procedure delegate.

Remarks

The **AddressOf** operator creates a function delegate that points to the function specified by *procedurename*. When the specified procedure is an instance method then the function delegate refers to both the instance and the method so that when the function delegate is invoked the specified method of the specified instance is called.

The AddressOf operator can be used as the operand of a delegate constructor or it can be used in a context in which the type of the delegate can be determined by the compiler.

Example

This example uses the **AddressOf** operator to designate a delegate to handle the **Click** event of a button.

```
Public Sub ButtonClickHandler(ByVal sender As Object, e As _
                              System.EventArgs)
' Implementation code omitted.
End Sub

' Add the following line to Sub Form1_Load().
   AddHandler Button1.Click, AddressOf ButtonClickHandler
```

'The following example uses the **AddressOf** operator to designate the startup function for a thread.

```
Imports System.Threading   ' Access threading namespace.

Public Sub CountSheep()
   Dim i As Integer = 1 ' Sheep don't count from 0.
   Do While (True) ' Endless loop.
      Console.WriteLine("Sheep " & i & " Baah")
      i = i + 1
      Thread.Sleep(1000) 'Wait 1 second.
   Loop
End Sub

Sub UseThread()
   Dim t As New System.Threading.Thread(AddressOf CountSheep)
   t.Start()
End Sub
```

See Also

Declare Statement | Function Statement | Sub Statement | Delegates and the AddressOf operator

And Operator

Performs a logical conjunction on two **Boolean** expressions, or bitwise conjunction on two numeric expressions.

```
result = expression1 And expression2
```

Parts

result
Required. Any **Boolean** or numeric expression. The result for **Boolean** comparison is the **Boolean** result of comparison of the two expressions. The result for numeric comparison is a numeric value resulting from the bitwise conjunction of two numeric expressions

expression1
Required. Any **Boolean** or numeric expression.

expression2
Required. Any **Boolean** or numeric expression.

Remarks

For **Boolean** comparison, if both *expression1* and *expression2* evaluate to **True**, *result* is **True**. If *expression1* evaluates to **True** and *expression2* evaluates to **False**, *result* is **False**. If *expression1* evaluates to **False**, and *expression2* evaluates to True, the *result* is **False.** The following table illustrates how *result* is determined:

If *expression1* is	**And *expression2* is**	**Value of *result* is**
True	**True**	**True**
True	**False**	**False**
False	**True**	**False**
False	**False**	**False**

When applied to numeric values, the **And** operator performs a bitwise comparison of identically positioned bits in two numeric expressions and sets the corresponding bit in *result* according to the following table:

If bit in expression1 is	**And bit in expression2 is**	**The result is**
0	0	0
0	1	0
1	0	0
1	1	1

> **Note** Since the logical/bitwise operators have a lower precedence than other arithmetic and relational operators, any bitwise operations should be enclosed in parentheses to ensure accurate execution.

If the operands consist of one **Boolean** expression and one numeric expression, the result **Boolean** expression will be converted to a numeric value (-1 for True, and 0 for False) and the bitwise operation will result.

Example

This example uses the **And** operator to perform a logical conjunction on two expressions. The result is a **Boolean** value that represents whether the entire conjoined expression is true.

```
Dim A As Integer = 10
Dim B As Integer = 8
Dim C As Integer = 6
Dim myCheck As Boolean
myCheck = A > B And B > C   ' Returns True.
myCheck = B > A And B > C   ' Returns False.
```

This example uses the **And** operator to perform logical conjunction of the individual bits of two numeric expressions. The bit in the result pattern is set if the corresponding bits in the operands are both set.

```
Dim A As Integer = 10
```

```
Dim B As Integer = 8
Dim C As Integer = 6
Dim myCheck As Integer
myCheck = (A And B)   ' Returns 8.
myCheck = (A And C)   ' Returns 2.
myCheck = (B And C)   ' Returns 0.
```

See Also

Logical/Bitwise Operators | Operator Precedence in Visual Basic | Operators Listed by Functionality | AndAlso Operator | Logical Operators

AndAlso Operator

Performs short-circuiting logical conjunction on two expressions.

```
result = expression1 AndAlso expression2
```

Parts

result
Required. Any **Boolean** expression. The result is the **Boolean** result of comparison of the two expressions.
expression1
Required. Any **Boolean** expression.
expression2
Required. Any **Boolean** expression.

Remarks

A logical operation is said to be *short-circuiting* if the compiled code can bypass the evaluation of one expression depending on the result of another expression. If the result of the first expression evaluated determines the final result of the operation, there is no need to evaluate the other expression, because it cannot change the final result. Short-circuiting can improve performance if the bypassed expression is complex, or if it involves procedure calls.

If both *expression1* and *expression2* evaluate to **True**, *result* is **True**. If *expression1* evaluates to True and *expression2* evaluates to **False**, *result* is **False**. If *expression1* evaluates to **False**, *expression2* is not evaluated, and *result* is **False** (the operator is said to have short-circuited the expression). The following table illustrates how *result* is determined:

If *expression1* is	**And *expression2* is**	**Value of *result* is**
True	**True**	**True**
True	**False**	**False**
False	(not evaluated)	**False**

Example

This example uses the **AndAlso** operator to perform a logical conjunction on two expressions. The result is a **Boolean** value that represents whether the entire conjoined expression is true. If the first expression is **False**, the second is not evaluated.

```
Dim A As Integer = 10
Dim B As Integer = 8
Dim C As Integer = 6
Dim myCheck As Boolean
myCheck = A > B AndAlso B > C   ' True.
myCheck = B > A AndAlso B > C   ' False. Second expression not evaluated.
myCheck = A > B AndAlso C > B   ' False. Second expression evaluated.

Public Function FindValue(ByVal Arr() As Double, _
                          ByVal SearchValue As Double) As Double
   Dim I As Integer = 0
   While I <= UBound(Arr) AndAlso Arr(I) <> SearchValue
   ' If I is greater than UBound(Arr), SearchValue is not checked.
      I += 1
   End While
   If I >= UBound(Arr) Then I = -1
   Return I
End Function
```

Logical/Bitwise Operators | Operator Precedence in Visual Basic | Operators Listed by Functionality | And Operator | Logical Operators

GetType Operator

Returns a **Type** object for the specified type. The **Type** object can be used to retrieve information about the type such as its properties, methods, and events.

```
GetType(typename)
```

Parameters

typename
The name of the type for which information is desired.

Remarks

The **GetType** operator returns the type object for the specified *typename*. If you want to get the type object of an object variable, use Type.GetType Method.

Example

The following examples show the **GetType** operator in use.

```
GetType(Integer)   ' Returns the integer Type object.
GetType(String())   ' Returns the Type object for 1D string arrays.
```

See Also

Operator Precedence in Visual Basic | Operators Listed by Functionality | Operators

Is Operator

Compares two object reference variables.

```
result = object1 Is object2
```

Parts

result
Required. Any **Boolean** value.
object1
Required. Any **Object** name.
object2
Required. Any **Object** name.

Remarks

The **Is** operator determines if two object references refer to the same object. However, it does not perform value comparisons. If *object1* and *object2* both refer to the same object, *result* is **True**; if they do not, *result* is **False**.

Example

This example uses the **Is** operator to compare two object references. The object variable names are generic and used for illustration purposes only. The result is a **Boolean** value representing whether the two objects are identical.

```
Dim myObject As New Object
Dim otherObject As New Object
Dim yourObject, thisObject, thatObject As Object
Dim myCheck As Boolean
yourObject = myObject
thisObject = myObject
thatObject = otherObject
myCheck = yourObject Is thisObject   ' Returns True.
myCheck = thatObject Is thisObject   ' Returns False.
myCheck = myObject Is thatObject ' Returns False, if myObject is not thatObject.
```

See Also

Comparison Operators | Operator Precedence in Visual Basic | Operators Listed by Functionality | Operators

Like Operator

Compares two strings.

```
result = string Like pattern
```

Parts

result
Required. Any **Boolean** variable. The result is a **Boolean** value indicating whether or not the *string* matches the *pattern*.
string
Required. Any **String** expression.
pattern
Required. Any **String** expression conforming to the pattern-matching conventions described in Remarks.

Remarks

If *string* matches *pattern*, *result* is **True**; if there is no match, *result* is **False**. If both *string* and *pattern* are an empty string. the result is **True**. Otherwise, if either *string* or *pattern* is an empty string, the result is **False**.

The behavior of the **Like** operator depends on the **Option Compare** statement. The default string-comparison method for each module is **Option Compare Binary**.

Built-in pattern matching provides a versatile tool for string comparisons. The pattern-matching features allow you to match strings using wildcard characters, character lists, or character ranges, in any combination. The following table shows the characters allowed in *pattern* and what they match:

Characters in *pattern*	**Matches in *string***
?	Any single character
*****	Zero or more characters
#	Any single digit (0–9)
[*charlist*]	Any single character in *charlist*
[**!***charlist*]	Any single character not in *charlist*

A group of one or more characters (*charlist*) enclosed in brackets (**[ ]**) can be used to match any single character in *string* and can include almost any character code, including digits.

> **Note** To match the special characters left bracket (**[**), question mark (**?**), number sign (**#**), and asterisk (*****), enclose them in brackets. The right bracket (**]**) can't be used within a group to match itself, but it can be used outside a group as an individual character.

By using a hyphen (**–**) to separate the upper and lower bounds of the range, *charlist* can specify a range of characters. For example, `[A-Z]` results in a match if the corresponding character position in *string* contains any uppercase letters in the range *A*–*Z*. Multiple ranges are included within the brackets without delimiters.

The meaning of a specified range depends on the character ordering valid at run time (as determined by **Option Compare** and the locale setting of the system the code is running on). Using **Option Compare Binary**, the range `[A-E]` matches *A*, *B*, *C*, *D*, and *E*. With **Option Compare Text**, `[A-E]` matches *A*, *a*, À, à, *B*, *b*, *C*, *c*, *D*, *d*, *E*, and *e*. The range does not match Ê or ê because accented characters fall after unaccented characters in the sort order.

Other important rules for pattern matching include the following:

- An exclamation point (**!**) at the beginning of *charlist* means that a match is made if any character except the characters in *charlist* is found in *string*. When used outside brackets, the exclamation point matches itself.
- A hyphen (**–**) can appear either at the beginning (after an exclamation point if one is used) or at the end of *charlist* to match itself. In any other location, the hyphen identifies a range of characters delimited by the characters on either side of the hyphen.
- When a range of characters is specified, they must appear in ascending sort order (that is, from lowest to highest). Thus, `[A-Z]` is a valid pattern, but `[Z-A]` is not.
- The character sequence `[]` is considered a zero-length string ("").

In some languages, there are special characters in the alphabet that represent two separate characters. For example, several languages use the character æ to represent the characters *a* and *e* when they appear together. The **Like** operator recognizes that the single special character and the two individual characters are equivalent.

When a language that uses a special character is specified in the system locale settings, an occurrence of the single special character in either *pattern* or *string* matches the equivalent two-character sequence in the other string. Similarly, a single special character in *pattern* enclosed in brackets (by itself, in a list, or in a range) matches the equivalent two-character sequence in *string*.

Example

This example uses the **Like** operator to compare a string to a pattern. The result is a **Boolean** value representing whether the string fits the pattern.

```
Dim myCheck As Boolean
myCheck = "F" Like "F"   ' Does "F" match "F"? Returns True.
myCheck = "F" Like "f"   ' Does "F" match "f"? Returns False.
myCheck = "F" Like "FFF"   ' Does "F" match "FFF"? Returns False.
myCheck = "aBBBa" Like "a*a"   ' Does "aBBBa" have a "a" at the
   ' beginning, an "a" at the end, and any number of characters in
   ' between? Returns True.
myCheck = "F" Like "[A-Z]"   ' Does "F" occur in the set of
   ' characters from A to Z? Returns True.
myCheck = "F" Like "[!A-Z]"     ' Does "F" NOT occur in the set of
   ' characters from A to Z? Returns False.
myCheck = "a2a" Like "a#a"     ' Does "a2a" begin and end with an
   ' "a" and have any single-digit number inbetween? Returns True.
myCheck = "aM5b" Like "a[L-P]#[!c-e]" ' Does "aM5b" fit the following
   ' pattern: Begins with "a", has and character from the set L through
   ' P, followed byb any single-digit number, and finally contains any
   ' character excluded from the character set c through e. Returns True.
myCheck = "BAT123khg" Like "B?T*"  ' Does "BAT123khg" fit the
   ' following pattern: Begins with "B", followed by any single
   ' character, followed by a "T" and finally zero or more characters
   ' of any type. Returns True.
myCheck = "CAT123khg" Like "B?T*"  ' Does "CAT123khg" fit the
   ' following pattern: Begins with "B", followed by any single
   ' character, followed by a "T" and finally zero or more characters
   ' of any type. Returns False.
```

Comparison Operators | InStr Function | Operator Precedence in Visual Basic | Operators Listed by Functionality | Option Compare Statement | StrComp Function | Operators

Mod Operator

Divides two numbers and returns only the remainder.

```
number1 Mod number2
```

Parts

number1
Required. Any numeric expression.
number2
Required. Any numeric expression.

Result

The result is the remainder left after division is performed on *number1* and *number2*.

Supported Types

Byte, **Short**, **Integer**, **Long**, **Single**, **Double**, **Decimal**

Remarks

The **Mod** operator divides *number1* by *number2* and returns only the remainder as *result*. For example, in the following expression, `A` (*result*) equals 2.

```
A = 8 Mod 3
```

If *number1* or *number2* are floating-point values, then division is carried out and the floating-point remainder is returned. The data type of the result is the same as that of the data type with the greatest range. The order of range, from least to greatest range, is Byte, Short, Integer, Long, Single, Double, and Decimal.

If any expression is stated as Nothing, or Empty, it is treated as zero. If division by zero occurs, the **Mod** operation returns **NaN (Not a Number)**.

`A Mod B` is the equivalent of `A - Int(A / B) * B + CLng(Math.Sign(A) <> Math.Sign(B)) * B`

Example

This example uses the **Mod** operator to divide two numbers and return only the remainder. If either number is a floating-point number, the result is a floating-point number representing the remainder.

```
Dim myResult As Double
myResult = 10 Mod 5   ' Returns 0.
myResult = 10 Mod 3   ' Returns 1.
myResult = 12 Mod 4.3   ' Returns 3.4.
myResult = 12.6 Mod 5   ' Returns 2.6.
myResult = 47.9 Mod 9.35   ' Returns 1.15.
```

See Also

Arithmetic Operators | Operator Precedence in Visual Basic | Operators Listed by Functionality | Arithmetic Operators

Not Operator

Performs logical negation on a **Boolean** expression, or bitwise negation on a numeric expression.

```
result = Not expression
```

Parts

result
Required. Any **Boolean** or numeric expression.
expression
Required. Any **Boolean** or numeric expression.

Remarks

For **Boolean** expressions, the following table illustrates how *result* is determined:

If *expression* is	Then *result* is
True	**False**
False	**True**

For numeric expressions, the **Not** operator inverts the bit values of any numeric expression and sets the corresponding bit in *result* according to the following table:

If bit in *expression* is	Then bit in *result* is
0	1
1	0

> **Note** Since the logical/bitwise operators have a lower precedence than other arithmetic and relational operators, any bitwise operations should be enclosed in parentheses to ensure accurate execution.

Example

This example uses the **Not** operator to perform logical negation on a **Boolean** expression. The result is a **Boolean** value representing whether the expression is false. That is, if the expression is false, the result of the **Not** operator is true.

```
Dim A As Integer = 10
Dim B As Integer = 8
Dim C As Integer = 6
Dim myCheck As Boolean
myCheck = Not(A > B)   ' Returns False.
myCheck = Not(B > A)   ' Returns True.
```

This example uses the **Not** operator to perform logical negation of the individual bits of two numeric expressions. The bit in the result pattern is set to the reverse of the corresponding bit in the operand pattern, including the sign bit.

```
Dim A As Integer = 10
Dim B As Integer = 8
Dim C As Integer = 6
Dim myCheck As Integer
myCheck = (Not A)   ' Returns -11.
myCheck = (Not B)   ' Returns -9.
myCheck = (Not C)   ' Returns -7.
```

Logical/Bitwise Operators | Operator Precedence in Visual Basic | Operators Listed by Functionality | Logical Operators

Or Operator

Used to perform a logical disjunction on two **Boolean** expressions, or bitwise disjunction on two numeric values..

```
result = expression1 Or expression2
```

Parts

result
Required. Any **Boolean** or numeric expression. For **Boolean** comparison the result is the logical disjunction of two expressions. For bitwise operations the result is a numeric value resulting from the bitwise disjunction of two numeric expressions.
expression1
Required. Any **Boolean** or numeric expression.
expression2
Required. Any **Boolean** or numeric expression of the same type as *expression1*.

Remarks

For **Boolean** comparison, if either *expression1* or *expression2* evaluates to **True**, *result* is **True.** If *expression1* evaluates to **True**, and *expression2* evaluates to **False** the *result* is **True**. The following table illustrates how *result* is determined:

If *expression1* is	**And *expression2* is**	**Then *result* is**
True	**True**	**True**
True	**False**	**True**
False	**True**	**True**
False	**False**	**False**

For bitwise operations, the **Or** operator performs a bitwise comparison of identically positioned bits in two numeric expressions and sets the corresponding bit in *result* according to the following table:

If bit in *expression1* is	**And bit in *expression2* is**	**Then *result* is**
0	0	0
0	1	1
1	0	1
1	1	1

> **Note** Since the logical/bitwise operators have a lower precedence than other arithmetic and relational operators, any bitwise operations should be enclosed in parentheses to ensure accurate execution.

If the operands consist of one **Boolean** expression and one numeric expression, the result **Boolean** expression will be converted to a numeric value (-1 for True, and 0 for False) and the bitwise operation will result.

Example

This example uses the **Or** operator to perform logical disjunction on two expressions. The result is a **Boolean** value that represents whether either of the two expressions is true.

```
Dim A As Integer = 10
Dim B As Integer = 8
Dim C As Integer = 6
Dim myCheck As Boolean
myCheck = A > B Or B > C   ' Returns True.
myCheck = B > A Or B > C   ' Returns True.
myCheck = B > A Or C > B   ' Returns False.
```

This example uses the **Or** operator to perform logical disjunction of the individual bits of two numeric expressions. The bit in the result pattern is set if either of the corresponding bits in the operands are set.

```
Dim A As Integer = 10
Dim B As Integer = 8
```

```
Dim C As Integer = 6
Dim myCheck As Integer
myCheck = (A Or B)   ' Returns 10.
myCheck = (A Or C)   ' Returns 14.
myCheck = (B Or C)   ' Returns 14.
```

See Also

Logical/Bitwise Operators | Operator Precedence in Visual Basic | Operators Listed by Functionality | OrElse Operator | Logical Operators

OrElse Operator

Used to perform short-circuiting logical disjunction on two expressions.

```
result = expression1 OrElse expression2
```

Parts

result
Required. Any **Boolean** expression.
expression1
Required. Any **Boolean** expression.
expression2
Required. Any **Boolean** expression.

Remarks

A logical operation is said to be *short-circuiting* if the compiled code can bypass the evaluation of one expression depending on the result of another expression. If the result of the first expression evaluated determines the final result of the operation, there is no need to evaluate the other expression, because it cannot change the final result. Short-circuiting can improve performance if the bypassed expression is complex, or if it involves procedure calls.

If either *expression1* or *expression2* evaluates to **True**, *result* is **True.** If *expression1* evaluates to **True**, *expression2* is not evaluated, and *result* is **True** (the operator is said to have short-circuited the expression). The following table illustrates how *result* is determined:

If *expression1* is	**And *expression2* is**	**Then *result* is**
True	(not evaluated)	**True**
False	**True**	**True**
False	**False**	**False**

Example

This example uses the **OrElse** operator to perform logical disjunction on two expressions. The result is a **Boolean** value that represents whether either of the two expressions is true. If the first expression is **True**, the second is not evaluated.

```
Dim A As Integer = 10
Dim B As Integer = 8
Dim C As Integer = 6
Dim myCheck As Boolean
myCheck = A > B OrElse B > C   ' True. Second expression is not evaluated.
myCheck = B > A OrElse B > C   ' True. Second expression is evaluated.
myCheck = B > A OrElse C > B   ' False.

If MyFunction(5) = True OrElse MyOtherFunction(4) = True Then
' If MyFunction(5) is True, MyOtherFunction(4) is not called.
   ' Insert code to be executed.
End If
```

See Also

Logical/Bitwise Operators | Operator Precedence in Visual Basic | Operators Listed by Functionality | Or Operator | Logical Operators

Xor Operator

Performs a logical exclusion operation on two **Boolean** expressions, or a bitwise exclusion on two numeric expressions..

```
result = expression1 Xor expression2
```

Parts

result
Required. Any **Boolean** or numeric variable. The result for **Boolean** comparison is the logical exclusion of two expressions. For bitwise operations the result is a numeric value resulting from the bitwise exclusion of two numeric expressions

expression1
Required. Any **Boolean** or numeric expression.

expression2
Required. Any **Boolean** or numeric expression of the same type as *expression1*.

Remarks

For **Boolean** comparisons, if one and only one of the expressions evaluates to **True**, *result* is **True**. Otherwise, *result* is **False**. If either expression is stated as Nothing, that expression is evaluated as **False**.

If *expression1* is	**And *expression2* is**	**Then *result* is**
True	**True**	**False**
True	**False**	**True**
False	**True**	**True**
False	**False**	**False**

For numeric expressions, the **Xor** operator performs as a bitwise operator. A bitwise comparison of two expressions using exclusive-or logic to form the result, as shown in the following table:

If bit in *expression1* is	**And bit in *expression2* is**	**Then *result* is**
0	0	0
0	1	1
1	0	1
1	1	0

> **Note** Since the logical/bitwise operators have a lower precedence than other arithmetic and relational operators, any bitwise operations should be enclosed in parentheses to ensure accurate execution.

If the operands consist of one **Boolean** expression and one numeric expression, the result **Boolean** expression will be converted to a numeric value (-1 for True, and 0 for False) and the bitwise operation will result.

Example

This example uses the **Xor** operator to perform logical exclusion on two expressions. The result is a **Boolean** value representing whether *only* one of the expressions is true.

```
Dim A As Integer = 10
Dim B As Integer = 8
Dim C As Integer = 6
Dim myCheck As Boolean
myCheck = A > B Xor B > C   ' Returns False.
myCheck = B > A Xor B > C   ' Returns True.
myCheck = B > A Xor C > B   ' Returns False.
```

This example uses the **Xor** operator to perform logical exclusion of the individual bits of two numeric expressions. The bit in the result pattern is set if only one of the corresponding bits in the operands are set.

```
Dim A As Integer = 10
Dim B As Integer = 8
```

```
Dim C As Integer = 6
Dim myCheck As Integer
myCheck = (A Xor B)   ' Returns 2.
myCheck = (A Xor C)   ' Returns 12.
myCheck = (B Xor C)   ' Returns 14.
```

Comparison Operators

Compares expressions.

```
result = expression1 comparisonoperator expression2
result = object1 Is object2
result = string Like pattern
```

Parts

result
Required. Any numeric variable. The result is a **Boolean** value representing the result of the comparison.
expression
Required. Any expression.
comparisonoperator
Required. Any comparison operator.
object
Required. Any reference object name.
string
Required. Any **String** expression.
pattern
Required. Any **String** expression or range of characters.

Remarks

The following table contains a list of the comparison operators and the conditions that determine whether *result* is **True** or **False.**

Operator	True if	False if
< (Less than)	*expression1 < expression2*	*expression1 >= expression2*
<= (Less than or equal to)	*expression1 <= expression2*	*expression1 > expression2*
> (Greater than)	*expression1 > expression2*	*expression1 <= expression2*
>= (Greater than or equal to)	*expression1 >= expression2*	*expression1 < expression2*
= (Equal to)	*expression1 = expression2*	*expression1 <> expression2*
<> (Not equal to)	*expression1 <> expression2*	*expression1 = expression2*

Note The **Is** and **Like** operators have specific comparison functionality that differs from the operators in the table.

When an expression of type **Single** is compared to one of type **Double**, the **Single** expression is converted to **Double**. This behavior is opposite to the behavior found in Visual Basic 6.

Similarly, when an expression of type **Decimal** is compared with an expression of type **Single** or **Double**, the **Decimal** expression will be converted to **Single** or **Double**. For **Decimal** expressions, any fractional value less than 1E-28 may be lost. Such fractional value loss may cause two values to compare as equal when they are not. For this reason, care should be taken when using equality (=) to compare two floating-point variables. It is better to test that the absolute value of the difference between the two numbers is less than a small acceptable tolerance.

Comparing Strings

When Strings are compared, the string expressions are evaluated based on their alphabetical sort order. The sort order for strings is evaluated based upon the **Option Compare** setting.

Option Compare Binary results in string comparisons based on a sort order derived from the internal binary representations of the characters. Sort order is determined by the code page. In the following example, a typical binary sort order is shown:

```
A < B < E < Z < a < b < e < z < À < Ê < Ø < à < ê < ø
```

Option Compare Text results in string comparisons based on a case-insensitive, textual sort order determined by your system's locale. When you sort the same characters using **Option Compare Text**, the following text sort order is produced:

(A=a) < (À= à) < (B=b) < (E=e) < (Ê= ê) < (Ø = ø) < (Z=z)

Typeless programming with comparison operators

The use of comparison operators with **Object** expressions is not allowed under **Option Strict On**. When **Option Strict** is **Off**, and *expression1* or *expression2* are **Object** expressions, their runtime type determines how they are compared. The following table shows how the expressions are compared and the result from the comparison, depending on the runtime type of the operands:

If operands are:	**Comparison will be:**
Both strings	Sort comparison based on string sorting characteristics.
Both numeric values	Objects will be converted to **Double**, and numeric comparison performed.
One numeric value, and one **String**	The **String** is converted to a **Double** and numeric comparison i s performed. If the **String** cannot be converted to **Double**, an **In validCastException** will be thrown.
Either or both are reference types other than **String**	An **InvalidCastException** will be thrown.

For numeric comparisons, **Nothing** is treated as 0. For string comparisons, **Nothing** is treated as "".

Example

This example shows various uses of comparison operators, which you use to compare expressions. Comparison operators return a **Boolean** result that represents whether or not the stated expression is true. When the > and < operators are applied to strings, the comparison is made between the normal alphabetical sorting order of the strings. This may be dependent on locale. Whether the sort is case-sensitive or not depends on the Option Compare setting.

```
Dim myResult As Boolean
myResult = 45 < 35   ' Returns False.
myResult = 45 = 45   ' Returns True.
myResult = 4 <> 3   ' Returns True.
myResult = "5" > "4444"   ' Returns True.
```

Count Property

Returns an integer containing the number of objects in a collection. Read-only.

```
Overridable Public ReadOnly Property Count() As Integer
```

Example

This example uses the **Collection** object's **Count** property to specify how many iterations are required to remove all the elements of the collection called `Classes1`. When collections are numerically indexed, the base is 1 by default. Since collections are reindexed automatically when a removal is made, the following code removes the first member on each iteration.

```
Dim Num As Long
Dim Classes1 As New Collection()
For Num = 1 To Classes1.Count   ' Remove name from the collection.
   Classes1.Remove(1)   ' Default collection numeric indexes.
Next
```

Requirements

Namespace: Microsoft.VisualBasic

Class: Collection

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Add Method | Item Property | Remove Method

Applies To

Collection Object

DateString Property

Returns or sets a **String** value representing the current date according to your system.

```
Public Property DateString As String
```

Exceptions/Errors

Exception type	Error number	Condition
InvalidCastException	5	Invalid cast.

Remarks

DateString always returns the system date as "MM-dd-yyyy", which uses the abbreviated month name. The accepted formats for setting the date are "M-d-yyyy", "M-d-y", "M/d/yyyy", and "M/d/y".

If you attempt to set **DateString** with an invalid value, an **InvalidCastException** occurs.

To get or set the current system time as a **String**, use the **TimeString** property.

To access the current system date as a **Date**, use the **Today** property.

Example

This example uses the **DateString** property to display the current system date.

```
MsgBox("The current date is " & DateString)
```

Requirements

Namespace: Microsoft.VisualBasic

Module: DateAndTime

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Because **DateString** is a member of a module, rather than of a class, you do not need to create an object on which to access **DateString**.

See Also

Now Property | TimeString Property | Today Property | System Namespace | DateTime Structure | ArgumentException Class

Description Property

Returns or sets a **String** expression containing a descriptive string associated with an error. Read/write.

For the **Err** object, returns or sets a descriptive string associated with an error.

```
Public Property Description() As String
```

Remarks

The **Description** property setting consists of a short description of the error. Use this property to alert the user to an error that you can't or don't want to handle. When generating a user-defined error, assign a short description of your error to the **Description** property. If the **Description** property isn't filled in, and the value of the Number property corresponds to a Visual Basic run-time error, then the string returned by the ErrorToString function is set in the **Description** property when the error is generated.

Example

This example assigns a user-defined message to the **Description** property of the **Err** object.

```
On Error Resume Next
Err.Raise(60000)
Err.Description = "Your Widget needs a new Frob!"
MsgBox(Err.Description)
```

Requirements

Namespace: Microsoft.VisualBasic

Class: ErrObject

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

ErrorToString Function | HelpContext Property | HelpFile Property | LastDLLError Property | Number Property | Source Property | Version Property

Applies To

Err Object

Erl Property

Returns an integer indicating the line number of the last executed statement. Read-only.

```
Public ReadOnly Property Erl() As Integer
```

Remarks

If Visual Basic encounters no line numbers, it returns 0.

Example

This example uses the **Erl** property to indicate the line number.

```
10:     On Error Resume Next
20:     Err.Raise(60000)
' Returns 20.
30:     MsgBox(Erl())
```

Smart Device Developer Notes

This property is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Class: ErrObject

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

ErrorToString Function

Applies To

Err Object

HelpContext Property

Returns or sets an **Integer** containing the context ID for a topic in a Help file. Read/write.

```
Public Property HelpContext() As Integer
```

Remarks

The **HelpContext** property is used to display context-sensitive help for an application. If a help file is specified in **HelpFile**, the **HelpContext** property is used to automatically display the help file identified. If both the **HelpFile** and **HelpContext** properties are empty, the value of the Number property is checked. If the value of the **Number** property corresponds to a Visual Basic run-time error value, then the Visual Basic Help context ID for the error is used. If the value of the **Number** property doesn't correspond to a Visual Basic error, the contents screen for the Visual Basic Help file is displayed.

> **Note** You should write routines in your application to handle typical errors. When programming with an object, you can use the object's Help file to improve the quality of your error handling, or to display a meaningful message to your user if the error isn't recoverable.

Example

This example uses the **HelpContext** property of the **Err** object to show the Visual Basic Help topic for the `Overflow` error.

```
Dim Msg As String
Err.Clear
On Error Resume Next
Err.Raise(6)   ' Generate "Overflow" error.
If Err.Number <> 0 Then
   Msg = "Press F1 or HELP to see " & Err.HelpFile & " topic for" & _
   " the following HelpContext: " & Err.HelpContext
   MsgBox(Msg, , "Error:" )
End If
```

Requirements

Namespace: Microsoft.VisualBasic

Class: ErrObject

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Description Property | ErrorToString Function | HelpFile Property | LastDLLError Property | Number Property | Source Property

Applies To

Err Object

HelpFile Property

Returns or sets a **String** expression containing the fully qualified path to a Help file. Read/write.

```
Public Property HelpFile() As String
```

Remarks

If a Help file is specified by the **HelpFile** property, it is automatically called when the user presses the Help key (or the F1 key) in the error message dialog box. If the **HelpContext** property contains a valid context ID for the specified file, that topic is automatically displayed. If no **HelpFile** is specified, the Visual Basic Help file is displayed.

> **Note** You should write routines in your application to handle typical errors. When programming with an object, you can use the object's Help file to improve the quality of your error handling, or to display a meaningful message to your user if the error isn't recoverable.

Example

This example uses the **HelpFile** property of the **Err** object to start the Help system. By default, the **HelpFile** property contains the name of the Visual Basic Help file.

```
Dim Msg As String
Err.Clear
On Error Resume Next   ' Suppress errors for demonstration purposes.
Err.Raise(6)   ' Generate "Overflow" error.
Msg = "Press F1 or HELP to see " & Err.HelpFile & _
" topic for this error"
MsgBox (Msg, , "Error: ")
```

Requirements

Namespace: Microsoft.VisualBasic

Class: ErrObject

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Description Property | HelpContext Property | LastDLLError Property | Number Property | Source Property

Applies To

Err Object

Item Property

Returns a specific member of a **Collection** object either by position or by key.

```
ReadOnly Public Default Overloads Property Item( _
   ByVal Index As { Integer | Object } _
) As Object
```

Parameters

Object
An object expression that evaluates to an object in the **Collection** object.

Index
An expression that specifies the position of a member of the collection. If a numeric expression, *Index* must be a number from 1 to the value of the collection's **Count** property. If *Index* is a **String** expression, it must correspond to the key value specified when the member referred to was added to the collection.

Exceptions/Errors

Exception type	Error number	Condition
ArgumentException	5	Index doesn't match an existing member of the collection.
IndexOutOfRangeException	9	*Index* does not match an existing member of the collection.

Remarks

If *Index* doesn't match any existing member of the collection, an error occurs.

The **Item** property is the default property for a collection. Therefore, the following lines of code are equivalent:

```
Print MyCollection(1)
Print MyCollection.Item(1)
```

Example

This example uses the **Item** property to retrieve a reference to an object in a collection. Given that `birthdays` is a **Collection** object, the following code retrieves a reference to the objects representing Bill's birthday from the collection, using the key "Bill" as the *Index* arguments.

```
Dim birthdays As New Collection()
Dim aBirthday As DateTime
birthdays.Add(New DateTime(2001, 1, 12), "Bill")
aBirthday = birthdays("Bill")
MsgBox(aBirthday.ToString())
aBirthday = birthdays.Item("Bill")
MsgBox(aBirthday.ToString())
```

Note that the first call explicitly specifies the **Item** property, but the second does not. Both calls work because the **Item** property is the default for a **Collection** object. The reference, assigned to `aBirthday`, can be used to access the properties and methods of the specified object.

Requirements

Namespace: Microsoft.VisualBasic

Module: Collection

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Add Method | Count Property | Remove Method | IndexOutOfRangeException Class

Applies To

Collection Object

LastDLLError Property

Returns a system error code produced by a call to a dynamic-link library (DLL). Read-only.

```
ReadOnly Property LastDLLError() As Integer
```

Remarks

The **LastDLLError** property applies only to DLL calls made from Visual Basic code. When such a call is made, the called function usually returns a code indicating success or failure, and the **LastDLLError** property is filled. Check the documentation for the DLL's functions to determine the return values that indicate success or failure. Whenever the failure code is returned, the Visual Basic application should immediately check the **LastDLLError** property. No exception is raised when the **LastDLLError** property is set.

> **Note** The **LastDllError** property requires unmanaged code permission, which may affect its execution in partial trust situations. For more information, see SecurityPermission and Code Access Permissions.

Example

When pasted into a **UserForm** module, the following code causes an attempt to call a DLL function. The call fails because the argument that is passed in (a null pointer) generates an error, and in any event, SQL can't be cancelled if it isn't running. The code following the call checks the return of the call, and then prints at the **LastDLLError** property of the **Err** object to reveal the error code. On systems without DLLs, **LastDLLError** always returns zero.

```
Private Declare Function SQLCancel Lib "ODBC32.dll" _
(ByVal hstmt As Integer) As Long

Private Sub Update()
   Dim RetVal As Integer
   Dim myhandle As Integer
   ' Call with invalid argument.
   RetVal = SQLCancel(myhandle)
   ' Check for SQL error code.
   If RetVal = -2 Then
      ' Display the information code.
      MsgBox("Error code is :" & Err.LastDllError)
    End If
End Sub
```

Smart Device Developer Notes

This property always returns zero.

Requirements

Namespace: Microsoft.VisualBasic

Class: ErrObject

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Declare Statement | Description Property | Err Object | ErrorToString Function | HelpContext Property | HelpFile Property | Number Property | Source Property

Applies To

Err Object

Now Property

Returns a **Date** value containing the current date and time according to your system.

```
ReadOnly Public Property Now() As DateTime
```

Remarks

To set the system date, use the **Today** property. To set the system time, use the **TimeOfDay** property.

Example

This example uses the **Now** property to return the current system date and time.

```
Dim ThisMoment As Date
ThisMoment= Now   ' Assign current system date and time.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: DateAndTime

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Because **Now** is a member of a module, rather than of a class, you do not need to create an object on which to access **Now**.

See Also

Day Function | Hour Function | Minute Function | Month Function | Second Function | TimeOfDay Property | Weekday Function | Year Function | TimeOfDay Property | Today Property | Date Data Type | System Namespace | DateTime Structure | ArgumentOutOfRangeException Class

Number Property

Returns or sets a numeric value specifying an error. Read/write.

```
Public Property Number() As Integer
```

Remarks

When returning a user-defined error from an object, set **Err.Number** by adding the number you selected as an error code to the **VbObjectError** constant. For example, you use the following code to return the number 1051 as an error code:

```
Err.Raise(Number := VbObjectError + 1051, Source:= "SomeClass")
```

Example

This example illustrates a typical use of the **Number** property in an error-handling routine.

```
' Typical use of Number property.
Sub test()
   On Error GoTo out

   Dim x, y As Integer
   x = 1 / y   ' Create division by zero error.
   Exit Sub
   out:
   MsgBox(Err.Number)
   MsgBox(Err.Description)
   ' Check for division by zero error.
   If Err.Number = 11 Then
      y = y + 1
   End If
   Resume Next
End Sub
```

Requirements

Namespace: Microsoft.VisualBasic

Class: ErrObject

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Description Property | ErrorToString Function | HelpContext Property | HelpFile Property | LastDLLError Property | Source Property

Applies To

Err Object

ScriptEngine Property

Returns a string representing the runtime currently in use.

```
ReadOnly Public Property ScriptEngine As String
```

Remarks

The **ScriptEngine** property returns the string "VB".

You can use **ScriptEngine** when your application is running as a standalone program, in a script, or in a host application.

Example

The following example uses the **ScriptEngine** property and related properties to return a string describing the current run-time information:

```
Function GetRuntimeInfo() As String
   Dim Runtime As String = ""
   Runtime = ScriptEngine & " Version "
   Runtime = Runtime & CStr(ScriptEngineMajorVersion) & "."
   Runtime = Runtime & CStr(ScriptEngineMinorVersion) & "."
   Runtime = Runtime & CStr(ScriptEngineBuildVersion)
   Return Runtime   ' Return the current run-time information.
End Function
```

Smart Device Developer Notes

This property is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: Globals

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Because **ScriptEngine** is a member of a module, rather than of a class, you do not need to create an object on which to access **ScriptEngine**.

See Also

ScriptEngineBuildVersion Property | ScriptEngineMajorVersion Property | ScriptEngineMinorVersion Property

ScriptEngineBuildVersion Property

Returns an integer containing the build version number of the runtime currently in use.

```
ReadOnly Public Property ScriptEngineBuildVersion As Integer
```

Remarks

The returned value corresponds directly to the version information contained in the DLL for the current runtime.

You can use **ScriptEngineBuildVersion** when your application is running as a standalone program, in a script, or in a host application.

Example

The following example uses the **ScriptEngineBuildVersion** property and related properties to return a string describing the current run-time information:

```
Function GetRuntimeInfo() As String
   Dim Runtime As String = ""
   Runtime = ScriptEngine & " Version "
   Runtime = Runtime & CStr(ScriptEngineMajorVersion) & "."
   Runtime = Runtime & CStr(ScriptEngineMinorVersion) & "."
   Runtime = Runtime & CStr(ScriptEngineBuildVersion)
   Return Runtime   ' Return the current run-time information.
End Function
```

Smart Device Developer Notes

This property is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: Globals

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Because **ScriptEngineBuildVersion** is a member of a module, rather than of a class, you do not need to create an object on which to access **ScriptEngineBuildVersion**.

See Also

ScriptEngine Property | ScriptEngineMajorVersion Property | ScriptEngineMinorVersion Property

ScriptEngineMajorVersion Property

Returns an integer containing the major version number of the runtime currently in use.

```
ReadOnly Public Property ScriptEngineMajorVersion As Integer
```

Remarks

The returned value corresponds directly to the version information contained in the DLL for the current runtime.

You can use **ScriptEngineMajorVersion** when your application is running as a standalone program, in a script, or in a host application.

Example

The following example uses the **ScriptEngineMajorVersion** property and related properties to return a string describing the current run-time information:

```
Function GetRuntimeInfo() As String
   Dim Runtime As String = ""
   Runtime = ScriptEngine & " Version "
   Runtime = Runtime & CStr(ScriptEngineMajorVersion) & "."
   Runtime = Runtime & CStr(ScriptEngineMinorVersion) & "."
   Runtime = Runtime & CStr(ScriptEngineBuildVersion)
   Return Runtime   ' Return the current run-time information.
End Function
```

Smart Device Developer Notes

This property is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: Globals

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Because **ScriptEngineMajorVersion** is a member of a module, rather than of a class, you do not need to create an object on which to access **ScriptEngineMajorVersion**.

See Also

ScriptEngine Property | ScriptEngineBuildVersion Property | ScriptEngineMinorVersion Property

ScriptEngineMinorVersion Property

Returns an integer containing the minor version number of the runtime currently in use.

```
ReadOnly Public Property ScriptEngineMinorVersion As Integer
```

Remarks

The returned value corresponds directly to the version information contained in the DLL for the current runtime.

You can use **ScriptEngineMinorVersion** when your application is running as a standalone program, in a script, or in a host application.

Example

The following example uses the **ScriptEngineMinorVersion** property and related properties to return a string describing the current run-time information:

```
Function GetRuntimeInfo() As String
   Dim Runtime As String = ""
   Runtime = ScriptEngine & " Version "
   Runtime = Runtime & CStr(ScriptEngineMajorVersion) & "."
   Runtime = Runtime & CStr(ScriptEngineMinorVersion) & "."
   Runtime = Runtime & CStr(ScriptEngineBuildVersion)
   Return Runtime   ' Return the current run-time information.
End Function
```

Smart Device Developer Notes

This property is not supported.

Requirements

Namespace: Microsoft.VisualBasic

Module: Globals

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Because **ScriptEngineMinorVersion** is a member of a module, rather than of a class, you do not need to create an object on which to access **ScriptEngineMinorVersion**.

See Also

ScriptEngine Property | ScriptEngineBuildVersion Property | ScriptEngineMajorVersion Property

Source Property

Returns or sets a **String** expression specifying the name of the object or application that originally generated the error. Read/write.

```
Public Property Source() As String
```

Remarks

The **Source** property specifies a **String** expression representing the object that generated the error; the expression is usually the object's class name or process ID. Use the **Source** property to provide information when your code is unable to handle an error generated in an accessed object. For example, if you access Microsoft Excel and it generates a `Division by zero` error, Microsoft Excel sets **Err.Number** to its error code for that error and sets **Source** to "Excel.Application".

When the application is generating an error from code, **Source** is your application's programmatic ID. Within a class, **Source** should contain a name having the form *project.class*. When an unexpected error occurs in your code, the **Source** property is automatically filled in. For errors in a module, **Source** contains the project name.

Example

This example demonstrates the use of the **Source** property in a typical error handling routine. When an error is raised from Class1, the string "Class1" is assigned to the **Source** property of the **Err** object. This string is then displayed in an informative message indicating the source and number of the error.

```
Public Class Class1
   Public Sub MySub()
      On Error Resume Next
      Err.Raise(60000, "Class1")
      MsgBox(Err.Source & " caused an error of type " & Err.Number)
   End Sub
End Class
```

Requirements

Namespace: Microsoft.VisualBasic

Class: ErrObject

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Description Property | ErrorToString Function | GetObject Function | HelpContext Property | HelpContext Property | HelpFile Property | LastDLLError Property | Number Property | On Error Statement

Applies To

Err Object

TimeOfDay Property

Returns or sets a **Date** value containing the current time of day according to your system.

```
Public Property TimeOfDay() As DateTime
```

Remarks

The **Date** data type includes date components. When returning the system time, **TimeOfDay** sets these all to 1, so the returned value represents the first day of the year 1. When setting the system time, **TimeOfDay** ignores the date components.

To access the current system time as a **String**, use the **TimeString** property.

To get or set the current system date, use the **Today** property.

Example

This example uses the **TimeOfDay** property to return the current system time.

```
Dim MyTime As Date
MyTime = TimeOfDay   ' Return current system time.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: DateAndTime

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Because **TimeOfDay** is a member of a module, rather than of a class, you do not need to create an object on which to access **TimeOfDay**.

See Also

Timer Property | TimeString Property | Today Property | System Namespace | DateTime Structure | ArgumentException Class | ArgumentOutOfRangeException Class

Timer Property

Returns a **Double** value representing the number of seconds elapsed since midnight.

```
ReadOnly Public Property Timer() As Double
```

Remarks

The **Timer** property returns both the seconds and the milliseconds since midnight. The seconds are in the integral part of the return value, and the milliseconds are in the fractional part.

Example

This example uses the **Timer** property to pause the application. It can perform other processing during the pause.

```
Public Sub WaitFiveSeconds()
   If TimeOfDay >= #11:59:55 PM# Then
      MsgBox("The current time is within 5 seconds of midnight" & _
         vbCrLf & "The timer returns to 0.0 at midnight")
      Return
   End If
   Dim Start, Finish, TotalTime As Double
   If (MsgBox("Press Yes to pause for 5 seconds", MsgBoxStyle.YesNo)) = _
      MsgBoxResult.Yes Then
      Start = Microsoft.VisualBasic.DateAndTime.Timer
      Finish = Start + 5.0   ' Set end time for 5-second duration.
      Do While Microsoft.VisualBasic.DateAndTime.Timer < Finish
         ' Do other processing while waiting for 5 seconds to elapse.
      Loop
      TotalTime = Microsoft.VisualBasic.DateAndTime.Timer - Start
      MsgBox "Paused for " & TotalTime & " seconds"
   End If
End Sub
```

Note that you must qualify the **Timer** property with the **Microsoft.VisualBasic** namespace, because **Timer** is also a defined class in the **System.Threading**, **System.Timers**, and **System.Windows.Forms** namespaces.

Requirements

Namespace: Microsoft.VisualBasic

Module: DateAndTime

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Because **Timer** is a member of a module, rather than of a class, you do not need to create an object on which to access **Timer**.

See Also

Randomize Statement | TimeOfDay Property | Today Property | System Namespace | System.Windows.Forms Namespace | DateTime Structure | ArgumentException Class | ArgumentOutOfRangeException Class

TimeString Property

Returns or sets a **String** value representing the current time of day according to your system.

```
Public Property TimeString As String
```

Exceptions/Errors

Exception type	Error number	Condition
InvalidCastException	5	Invalid cast.

Remarks

TimeString always returns the system time as "HH:mm:ss", which is a 24-hour format.

If you attempt to set **TimeString** with an invalid value, an **InvalidCastException** occurs.

To get or set the current system date as a **String**, use the **DateString** property.

To access the current system time as a **Date**, use the **TimeOfDay** property.

Example

This example uses the **TimeString** property to display the current system time.

```
MsgBox("The current time is " & TimeString)
```

Requirements

Namespace: Microsoft.VisualBasic

Module: DateAndTime

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Because **TimeString** is a member of a module, rather than of a class, you do not need to create an object on which to access **TimeString**.

See Also

Now Property | DateString Property | TimeOfDay Property | System Namespace | DateTime Structure | ArgumentException Class

Today Property

Returns or sets a **Date** value containing the current date according to your system.

```
Public Property Today() As DateTime
```

Remarks

The **Date** data type includes time components. When returning the system date, **Today** sets all of these to 0, so the returned value represents midnight (00:00:00). When setting the system date, **Today** ignores the time components.

To access the current system date as a **String**, use the **DateString** property.

To get or set the current system time, use the **TimeOfDay** property.

Example

This example uses the **Today** property to return the current system date.

```
Dim MyDate As Date
MyDate = Today   ' Return current system date.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: DateAndTime

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Because **Today** is a member of a module, rather than of a class, you do not need to create an object on which to access **Today**.

Visual Basic Language

A-E Statements

The following table contains a listing of the Visual Basic .NET language statements.

AddHandler	Call	Class	Const
Declare	Delegate	Dim	Do...Loop
End	Enum	Erase	Error
Event	Exit		

See Also

F-P Statements | Q-Z Statements | Visual Basic Language and Run-Time Reference

AddHandler Statement

Associates an event with an event handler.

```
AddHandler event, AddressOf eventhandler
```

Parts

event
The name of the event to handle.
eventhandler
The name of a procedure that will handle the event.

Remarks

The **AddHandler** and **RemoveHandler** statements allow you to start and stop event handling at any time during program execution.

Example

```
Sub TestEvents()
   Dim Obj As New Class1()
   ' Associate an event handler with an event.
   AddHandler Obj.Ev_Event, AddressOf EventHandler
   Obj.CauseSomeEvent()   ' Ask the object to raise an event.
End Sub

Sub EventHandler()
   ' This procedure handles events raised by the object Obj.
   MsgBox("EventHandler caught event.")   ' Handle the event.
End Sub

Public Class Class1
   Public Event Ev_Event()   ' Declare an event.
   Sub CauseSomeEvent()
      RaiseEvent Ev_Event()   ' Raise an event.
   End Sub
End Class
```

See Also

RemoveHandler Statement | Handles | Events and Event Handlers | AddHandler and RemoveHandler

Call Statement

Transfers control to a **Sub** procedure, **Function** procedure, or dynamic-link library (DLL) procedure.

```
[ Call ] ProcedureName[(ArgumentList)]
```

Parts

ProcedureName
Required. Name of the procedure to call.

ArgumentList
Optional. List of variables or expressions representing arguments that are passed to the procedure when it is called. Multiple arguments are separated by commas. If you include *ArgumentList*, you must enclose it in parentheses.

Remarks

You are not required to use the **Call** keyword when calling a procedure; however, if you use the **Call** statement to call any intrinsic, DLL, or user-defined function, the function's return value is discarded.

Example

This example illustrates how the **Call** statement is used to transfer control to a **Sub** procedure, an intrinsic function, and a dynamic-link library (DLL) procedure.

```
' Call a Sub procedure.
Call PrintToDebugWindow("Hello World")
' The above statement passes control to the following Sub procedure.
Sub PrintToDebugWindow(ByVal AnyString As String)
   Debug.WriteLine(AnyString)   ' Print to the Output window.
End Sub

' Call a Visual Basic run-time function (Shell), discard the return value.
Call Shell("C:\WINNT\system32\calc.exe", AppWinStyle.NormalFocus)
' The preceding path is for Windows 2000;
' The Windows XP path C:\Windows\system32\calc.exe.

' Call a Microsoft Windows DLL procedure. The Declare statement must be
' Private in a class, not in a module.
Private Declare Sub MessageBeep Lib "User32" (ByVal N As Integer)
Sub CallMyDll()
   Call MessageBeep(-1)   ' Call Windows DLL procedure.
   MessageBeep(-1)   ' Call again without Call keyword.
End Sub
```

See Also

Declare Statement | Function Statement | Sub Statement

Class Statement

Declares the name of a class, as well as a definition of the variables, properties, events, and methods that comprise the class.

```
[ <attrlist> ] [ Public | Private | Protected | Friend |
Protected Friend ] [ Shadows ] [ MustInherit | NotInheritable ] _
Class name
   [ Inherits classname ]
   [ Implements interfacenames ]
   [ statements ]
End Class
```

Parts

attrlist
Optional. List of attributes that apply to this class. Multiple attributes are separated by commas.

Public
Optional. Entities declared with the **Public** modifier have public access. There are no restrictions on the use of public entities.

Private
Optional. Entities declared with the **Private** modifier have private access. A private entity is accessible only within its declaration context, including any nested entities.

Protected
Optional. Entities declared with the **Protected** keyword have protected access. They are accessible only from within their own class or from a derived class. Protected access can be specified only on members of classes. It is not a superset of friend access.

Friend
Optional. Entities declared with the **Friend** modifier have friend access. An entity with friend access is accessible only within the program that contains the entity declaration. Classes that do not specify an access modifier are declared as **Friend** by default.

Protected Friend
Optional. Entities declared with the **Protected Friend** modifiers have the union of protected and friend accessibility.

Shadows
Optional. Indicates that this class shadows an identically named programming element in a base class. You can shadow any kind of declared element with any other kind. A shadowed element is unavailable from within the derived class that shadows it, unless the shadowing element is inaccessible, for example if it is **Private**.

MustInherit
Optional. Indicates that non-shared members of the **Class** can only be accessed via derived classes. Instances of must-inherit classes cannot be created.

NotInheritable
Optional. Indicates that the **Class** is a class from which no further inheritance is allowed.

name
Required. Name of the **Class**; follows standard variable naming conventions.

Inherits
Optional. Indicates that this class inherits the members of another class. A class can inherit from only one other class.

classname
The name of base class that this class inherits.

Implements
Optional. Indicates that this class implements the members of an interface. If you use the **Implements** statement, it must immediately follow any **Inherits** statements after the **Class** statement, and you must implement every member defined by every interface you specify.

interfacenames
Required if the **Implements** statement is used. The names of the interfaces implemented by this class.

statements
Optional. Statements which comprise the variables, properties, events, methods and nested types of the class.

End Class
Terminates the **Class** block.

Each attribute in the *attrlist* part has the following syntax and parts:

```
attrname [({ attrargs | attrinit })]
```

***attrlist* Parts**

attrname
Required. Name of the attribute. Must be a valid Visual Basic identifier.
attrargs
Optional. List of positional arguments for this attribute. Multiple arguments are separated by commas.
attrinit
Optional. List of field or property initializers for this attribute. Multiple initializers are separated by commas.

Remarks

Classes that do not specify an access modifier are declared as **Friend** by default. Within a **Class** block, members are declared as either **Public**, **Private**, **Protected**, **Friend**, or **Protected Friend** using the appropriate declaration statements. Anything declared as **Private** is visible only within the **Class** block. Anything declared as **Public** is visible within the **Class** block, as well as by code outside the **Class** block. Anything not explicitly declared is **Public** by default, except for fields and constants, which default to **Private**. **Public** variables, sometimes called Fields, serve as properties of the class, as do properties explicitly declared using **Property** declarations. Default properties and methods for the class are specified in their declarations using the **Default** keyword. See the individual declaration statement topics for information on how this keyword is used.

Binding of unqualified names in nested classes will search the members of the class itself, then the members of its containing class, and so on out to the outermost containing class. Private members of outer classes can be referenced but an error will be given for references to instance members of containing classes.

Nested classes cannot inherit from their containing class.

Example

This example uses the **Class** Statement to define a class, in which variables, properties, methods and events can be created.

```
Public Class ThisClass
  ' [variable, property, method and event declarations]
End Class
```

See Also

Inherits Statement | Implements Statement | Interface Statement | Property Statement |
Object Lifetime: How Objects are Created and Destroyed | Understanding Classes

Const Statement

Used at module, class, structure, procedure, or block level to declare constants for use in place of literal values.

```
[ <attrlist> ] [{ Public | Protected | Friend | Protected Friend |
Private }] [ Shadows ] Const name [ As type ] = initexpr
```

Parts

attrlist
Optional. List of attributes that apply to the constants declared in this statement. Multiple attributes are separated by commas.

Public
Optional. Constants declared with the **Public** keyword have public access. There are no restrictions on the accessibility of public constants.

Protected
Optional. Constants declared with the **Protected** keyword have protected access. They are accessible only from within their own class or from a derived class. Protected access can be specified only on members of classes. It is not a superset of friend access.

Friend
Optional. Constants declared with the **Friend** keyword have friend access. They are accessible from within their declaration context and from anywhere else in the same program.

Protected Friend
Optional. Constants declared with the **Protected Friend** keywords have the union of protected and friend access. They can be used by code in the same program, as well as by code in derived classes. Protected friend access can be specified only on members of classes.

Private
Optional. Constants declared with the **Private** keyword have private access. They are accessible only from within their declaration context, including from members of any nested types such as procedures.

Shadows
Optional. Indicates that this constant shadows an identically named programming element, or set of overloaded elements, in a base class. You can shadow any kind of declared element with any other kind. A shadowed element is unavailable from within the derived class that shadows it, unless the shadowing element is inaccessible, for example if it is **Private**.

name
Required. Name of the constant. Must be a valid Visual Basic identifier. You can declare as many constants as you like in the same declaration statement, specifying the *name* and *initexpr* parts for each one. Multiple constants are separated by commas.

type
Optional unless **Option Strict** is **On**. Data type of the constant. Can be **Boolean**, **Byte**, **Char**, **Date**, **Decimal**, **Double**, **Integer**, **Long**, **Object**, **Short**, **Single**, **String**, or the name of an enumeration. You must use a separate **As** clause for each constant being defined.

You cannot use variables or functions in *initexpr*. However, you can use the conversion keywords such as **CInt** and **CDate**, and you can use the **AscW** and **ChrW** methods of the **Strings** class in the **Microsoft.VisualBasic** namespace.

If you do not specify *type*, the constant takes the data type of *initexpr*. If you do specify *type*, the data type of *initexpr* must be convertible to *type*.

If *type* is **Object**, *initexpr* must be **Nothing**.

initexpr
Required. Expression that is evaluated and assigned to the constant when it is created. Can consist of a literal; another constant that is already defined; a member of an enumeration; or any combination of literals, constants, and enumeration members. You can use arithmetic and logical operators to combine such elements.

Each attribute in the *attrlist* part has the following syntax and parts:

```
attrname [({ attrargs | attrinit })]
```

***attrlist* Parts**

attrname
Required. Name of the attribute. Must be a valid Visual Basic identifier.

attrargs
Optional. List of positional arguments for this attribute. Multiple arguments are separated by commas.
attrinit
Optional. List of field or property initializers for this attribute. Multiple initializers are separated by commas.

Remarks

Constants declared in a **Sub**, **Function**, or **Property** procedure are local to that procedure. A constant declared outside a procedure is defined throughout the class, module, or structure in which it is declared.

You can use a constant anywhere you can use an expression.

Example

This example uses the **Const** statement to declare constants for use in place of literal values.

```
' Constants are shared by default.
Const MyVar As Integer = 459
' Declare Public String constant -- valid only at class or module level.
Public Const MyString As String = "HELP"
' Declare Private Integer constant -- valid only at class or module level.
Private Const MyInt As Integer = 5
```

See Also

Enum Statement | #Const Directive | Dim Statement | ReDim Statement

Declare Statement

Used at module level to declare references to external procedures in a dynamic-link library (DLL).

```
[ <attrlist> ] [ Public | Private | Protected | Friend | Protected Friend ] [ Shadows ] _
Declare [ Ansi | Unicode | Auto ] [ Sub ] name Lib "libname" _
[ Alias "aliasname" ] [([ arglist ])]
```

-or-

```
[ <attrlist> ] [ Public | Private | Protected | Friend | Protected Friend ] [ Shadows ] _
Declare [ Ansi | Unicode | Auto ] [ Function ] name Lib "libname" _
[ Alias "aliasname" ] [([ arglist ])] [ As type ]
```

Parts

attrlist
Optional. List of attributes that apply to this procedure. Multiple attributes are separated by commas.

Public
Optional. Entities declared with the **Public** modifier have public access. There are no restrictions on the use of public entities.

Private
Optional. Entities declared with the **Private** modifier have private access. A private entity is accessible only within its declaration context, including any nested entities.

Protected
Optional. Entities declared with the **Protected** keyword have protected access. They are accessible only from within their own class or from a derived class. Protected access can be specified only on members of classes. It is not a superset of friend access.

Friend
Optional. Entities declared with the **Friend** modifier have friend access. An entity with friend access is accessible only within the program that contains the entity declaration.

Protected Friend
Optional. Entities declared with the **Protected Friend** modifiers have the union of protected and friend accessibility.

Shadows
Optional. Indicates that this procedure shadows an identically named programming element in a base class. You can shadow any kind of declared element with any other kind. A shadowed element is unavailable from within the derived class that shadows it, unless the shadowing element is inaccessible, for example if it is **Private**.

Ansi
Optional. Converts all strings to ANSI values. If no modifier is specified, **Ansi** is the default.

Unicode
Optional. Converts all strings to Unicode values.

Auto
Optional. Converts the strings according to common language runtime rules based on the name of the method (or the alias name, if specified).

Sub
Optional (either **Sub** or **Function** must appear). Indicates that the procedure does not return a value.

Function
Optional (either **Sub** or **Function** must appear). Indicates that the procedure returns a value that can be used in an expression.

name
Required. Any valid procedure name. Note that DLL entry points are case sensitive.

Lib
Required. Indicates that a DLL or code resource contains the procedure being declared. The **Lib** clause is required for all declarations.

libname
Required. Name of the DLL or code resource that contains the declared procedure.

Alias
Optional. Indicates that the procedure being called has another name in the DLL. This is useful when the external procedure name is the same as a keyword. You can also use **Alias** when a DLL procedure has the same name as a public variable, constant, or any other procedure in the same scope. **Alias** is also useful if any characters in the DLL procedure name are not allowed by the DLL naming convention.

aliasname

Optional. Name of the procedure in the DLL or code resource. If the first character is not a number sign (**#**), *aliasname* is the name of the procedure's entry point in the DLL. If (**#**) is the first character, all characters that follow must indicate the ordinal number of the procedure's entry point.

arglist
Optional. List of variables representing arguments that are passed to the procedure when it is called.

type
Optional. Data type of the value returned by a Function procedure; may be **Byte**, **Boolean**, **Char**, **Short**, **Integer**, **Long**, **Single**, **Double**, **Decimal**, **String** (variable length only), **Object**, or structure. Arrays of any type cannot be returned, but an object containing an array can.

> **Note** Functions declared with the **Declare** statement cannot return dates.

Each attribute in the *attrlist* part has the following syntax and parts:

```
attrname [({ attrargs | attrinit })]
```

attrlist Parts

attrname
Required. Name of the attribute. Must be a valid Visual Basic identifier.

attrargs
Optional. List of positional arguments for this attribute. Multiple arguments are separated by commas.

attrinit
Optional. List of field or property initializers for this attribute. Multiple initializers are separated by commas.

The *arglist* argument has the following syntax and parts:

```
[ <attrlist> ] [ Optional ] [ ByVal | ByRef ] [ ParamArray ] varname[( )] [ As type ]
```

arglist Parts

attrlist
Optional. List of attributes that apply to this argument. Multiple attributes are separated by commas.

Optional
Optional. Indicates that an argument is not required. If used, all subsequent arguments in *arglist* must also be optional and declared using the **Optional** keyword. **Optional** can't be used for any argument if **ParamArray** is used.

ByVal
Optional. Indicates that the argument is passed by value. **ByVal** is the default in Visual Basic.

ByRef
Optional. Indicates that the argument is passed by reference.

ParamArray
Optional. Used only as the last argument in *arglist* to indicate that the final argument is an **Optional** array of **Object** elements. The **ParamArray** keyword allows you to provide an arbitrary number of arguments. The **ParamArray** keyword can't be used with **ByVal**, **ByRef**, or **Optional**.

varname
Required. Name of the variable representing the argument being passed to the procedure; follows standard variable naming conventions.

( )
Required for array variables. Indicates that *varname* is an array.

type
Optional. Data type of the argument passed to the procedure; may be **Byte**, **Boolean**, **Char**, **Short**, **Integer**, **Long**, **Single**, **Double**, **Decimal**, **String** (variable length only), **Object**, a user-defined type, or an object type.

Remarks

For **Function** procedures, the data type of the procedure determines the data type it returns. You can use an **As** clause following *arglist* to specify the return type of the function. Within *arglist*, you can use an **As** clause to specify the data type of any of the arguments passed to the procedure.

> **Note** If the external procedure was created on a platform other than Visual Basic .NET, you must take care that the data types correspond. For example, if you declare a reference to a Visual Basic 6.0 procedure with an **Integer**

argument (two bytes in Visual Basic 6.0), you must identify that argument as **Short** in the **Declare** statement, because that is the two-byte integer type in Visual Basic .NET.

Example

The following example declares a function that returns the current user name.

```
Declare Function GetUserName Lib "advapi32.dll" Alias _
"GetUserNameA" (ByVal lpBuffer As String, ByRef nSize As Integer) As Integer
Function GetUser()
   Dim RetVal As Integer
   Dim UserName As String
   Dim Buffer As String
   Buffer = New String(CChar(" "), 25)
   RetVal = GetUserName(Buffer, 25)
   UserName = Strings.Left(Buffer, InStr(Buffer, Chr(0)) - 1)
   MsgBox(UserName)
End Function
```

The **DllImport** attribute provides an alternative way of using functions in unmanaged code. The following example declares an imported function without using a **Declare** statement.

```
' Add an Imports statement at the top of the class or module
' where the DllImport attribute will be used.
Imports System.Runtime.InteropServices
'...
<DllImport("KERNEL32.DLL", EntryPoint:="MoveFileW", SetLastError:=True, _
CharSet:=CharSet.Unicode, ExactSpelling:=True, _
CallingConvention:=CallingConvention.StdCall)> _
Public Shared Function _
MoveFile(ByVal src As String, ByVal dst As String) As Boolean
   ' This function copies a file from the path src to the path dst.
   ' Leave function empty - DLLImport attribute forces calls
   ' to MoveFile to be forwarded to MoveFileW in KERNEL32.DLL.
End Function
```

Delegate Statement

Used to declare a delegate. Delegates are a reference type that refers to a **Shared** method of a type or to an instance method of an object. Any procedure with matching parameters types and return type may be used to create an instance of this delegate class. The procedure can then later be invoked via the delegate instance.

```
[ <attrlist> ] [ Public | Private | Protected | Friend | Protected Friend ] _
[ Shadows ] Delegate [ Sub ] name [([ arglist ])]
```

-or-

```
[ <attrlist> ] [ Public | Private | Protected | Friend | Protected Friend ] _
[ Shadows ] Delegate [ Function ] name [([ arglist ])] As type
```

Parts

attrlist
Optional. List of attributes that apply to this delegate. Multiple attributes are separated by commas.

Public
Optional. Entities declared with the **Public** modifier have public access. There are no restrictions on the use of public entities.

Private
Optional. Entities declared with the **Private** modifier have private access. A private entity is accessible only within its declaration context, including any nested entities.

Protected
Optional. Entities declared with the **Protected** keyword have protected access. They are accessible only from within their own class or from a derived class. Protected access can be specified only on members of classes. It is not a superset of friend access.

Friend
Optional. Entities declared with the **Friend** modifier have friend access. An entity with friend access is accessible only within the program that contains the entity declaration.

Protected Friend
Optional. Entities declared with the **Protected Friend** modifiers have the union of protected and friend accessibility.

Shadows
Optional. Indicates that this delegate shadows an identically named programming element in a base class. You can shadow any kind of declared element with any other kind. A shadowed element is unavailable from within the derived class that shadows it, unless the shadowing element is inaccessible, for example if it is **Private**.

Sub
Optional, but either **Sub** or **Function** must appear. Declares this procedure as a delegate subroutine that does not return a value.

Function
Optional, but either **Sub** or **Function** must appear. Declares this procedure as a delegate function that returns a value.

name
Required. Name of the delegate type; follows standard variable naming conventions.

arglist
Optional. List of variables representing arguments that are passed to the procedure when it is called.

type
Optional. Data type of the return value.

Each attribute in the *attrlist* part has the following syntax and parts:

```
attrname [({ attrargs | attrinit })]
```

***attrlist* Parts**

attrname
Required. Name of the attribute. Must be a valid Visual Basic identifier.

attrargs
Optional. List of positional arguments for this attribute. Multiple arguments are separated by commas.

attrinit
Optional. List of field or property initializers for this attribute. Multiple initializers are separated by commas.

Each argument in the *arglist* part has the following syntax and parts:

```
[ <attrlist> ] [ ByVal | ByRef ] varname[( )] [ As type ]
```

arglist Parts

attrlist
Optional. List of attributes that apply to this argument. Multiple attributes are separated by commas.

ByVal
Optional. Indicates that the argument is passed by value. **ByVal** is the default in Visual Basic.

ByRef
Optional. Indicates that the argument is passed by reference.

varname
Required. Name of the variable representing the argument being passed to the procedure; follows standard variable naming conventions.

( )
Required for array variables. Indicates that *varname* is an array.

type
Optional. Data type of the argument passed to the procedure; may be **Byte**, **Boolean**, **Char**, **Short**, **Integer**, **Long**, **Single**, **Double**, **Decimal**, **Date**, **String** (variable length only), **Object**, a user-defined type, or an object type.

Remarks

The **Delegate** statement defines the parameter types and return type of a delegate class. Any procedure with matching parameters types and return type may be used to create an instance of this delegate class. The procedure can then later be invoked via the delegate instance, by calling the delegate's **Invoke** method.

Delegates, which can be declared at the namespace, module, or class level, cannot be declared within procedures.

Each delegate class defines a constructor that is passed the specification of an object method. An argument to a delegate constructor must be an expression of the form:

```
AddressOf [<expression>.]<methodname>
```

The compile-time type of the *expression* must be the name of a class or an interface that contains a method of the specified name whose signature matches the signature of the delegate class. The *methodname* can be either a shared method or an instance method. The *methodname* is not optional even if you create a delegate for the default method of the class.

Example

This example uses the **Delegate** statement to declare a delegate for comparing two integers and returning a Boolean. The `SelectionSort` method takes an instance of a delegate of this type and uses it to sort an integer array.

```
Public Class SortClass
   Delegate Function Compare(ByVal x As Integer, _
                             ByVal y As Integer) As Boolean

   Function CompareValues(ByVal X As Integer, _
                          ByVal Y As Integer) As Boolean
      If X > Y Then
         CompareValues = True
      Else
         CompareValues = False
      End If
   End Function

   Sub SelectionSort(ByVal IsGreaterThan As Compare, _
                     ByVal IntArray() As Integer)
      Dim MaxVal As Integer
      Dim MaxIndex As Integer
      Dim i, j As Integer

      ' Step through the elements in the array starting with the
```

```
        ' last element in the array.
        For i = UBound(IntArray) To 1 Step -1
           MaxVal = IntArray(i)
           MaxIndex = i
           For j = 1 To i
              ' Use the delegate to compare values.
              If IsGreaterThan.Invoke(IntArray(j), MaxVal) Then
                 MaxVal = IntArray(j)
                 MaxIndex = j
              End If
           Next j
           ' Use the delegate to compare values.
           If IsGreaterThan.Invoke(i, MaxIndex) Then
              IntArray(MaxIndex) = IntArray(i)
              IntArray(i) = MaxVal
           End If
        Next i
     End Sub
  End Class

  Class Class1
     Sub SortArray()
        Dim Sort As New SortClass()
        Dim arr1() As Integer = {1, 5, 3, 2, 7, 22, 5, 54, 12}
        Sort.SelectionSort(AddressOf Sort.CompareValues, arr1)
        MsgBox("Array sorted.")
     End Sub
  End Class

  ' Add a button to your main form and insert the following code
  ' into the Click event handlr.
     Private Sub Button1_Click(ByVal sender As System.Object, _
                               ByVal e As System.EventArgs) _
                               Handles Button1.Click
        Dim c As New Class1()
        c.SortArray()
     End Sub
```

AddressOf Operator | Events and Delegates

Dim Statement

Used at module, class, structure, procedure, or block level to declare and allocate storage space for variables.

```
[ <attrlist> ] [{ Public | Protected | Friend | Protected Friend |
Private | Static }] [ Shared ] [ Shadows ] [ ReadOnly ]
Dim [ WithEvents ] name[ (boundlist) ] [ As [ New ] type ] [ = initexpr ]
```

Parts

attrlist
Optional. List of attributes that apply to the variables declared in this statement. Multiple attributes are separated by commas.

Public
Optional. Variables declared with the **Public** keyword have public access. There are no restrictions on the accessibility of public variables.

You can use **Public** only at module, namespace, or file level. This means you can declare public variables in a source file or inside a module, class, or structure, but not inside a procedure. If you specify **Public**, you can optionally omit the **Dim** keyword.

Protected
Optional. Variables declared with the **Protected** keyword have protected access. They are accessible only from within their own class or from a derived class. Protected access is not a superset of friend access.

You can use **Protected** only at class level. This means you can declare protected variables inside a class but not inside a procedure, and not at module, namespace, or file level. You can use **Protected** only to declare members of the class. If you specify **Protected**, you can optionally omit the **Dim** keyword.

Friend
Optional. Variables declared with the **Friend** keyword have friend access. They are accessible from within their declaration context and from anywhere else in the same program.

You can use **Friend** only at module, namespace, or file level. This means you can declare friend variables in a source file or inside a module, class, or structure, but not inside a procedure. If you specify **Friend**, you can optionally omit the **Dim** keyword.

Protected Friend
Optional. Variables declared with the **Protected Friend** keywords have the union of protected and friend access. They can be used by code anywhere in the same program, by code in their own class, and by code in any derived classes.

You can use **Protected Friend** only at class level. This means you can declare protected friend variables inside a class but not inside a procedure, and not at module, namespace, or file level. You can use **Protected Friend** only to declare members of the class. If you specify **Protected Friend**, you can optionally omit the **Dim** keyword.

Private
Optional. Variables declared with the **Private** keyword have private access. They are accessible only from within their declaration context, including from members of any nested types such as procedures.

You can use **Private** only at module level. This means you can declare private variables inside a module, class, or structure, but not at namespace or file level and not inside a procedure. If you specify **Private**, you can optionally omit the **Dim** keyword.

Static
Optional. Variables declared with the **Static** keyword remain in existence and retain their latest values after termination of the procedure in which they are declared.

You can use **Static** only at procedure level. This means you can declare static variables inside a procedure or a block within a procedure, but not at class or module level. If you specify **Static**, you can optionally omit the **Dim** keyword.

You cannot specify **Static** together with either **Shared** or **Shadows** in the same variable declaration.

Shared
Optional. Indicates that this variable is shared. This means it is not associated with a specific instance of a class or structure. You can access a shared variable by qualifying it either with the class or structure name, or with the variable name of a specific instance of the class or structure.

You can use **Shared** only at module, namespace, or file level. This means you can declare shared variables in a source file or inside a module, class, or structure, but not inside a procedure. If you specify **Shared**, you can optionally omit the **Dim** keyword.

You cannot specify both **Static** and **Shared** in the same variable declaration.

Shadows

Optional. Indicates that this variable shadows an identically named programming element, or set of overloaded elements, in a base class. You can shadow any kind of declared element with any other kind. A shadowed element is unavailable from within the derived class that shadows it, unless the shadowing element is inaccessible, for example if it is **Private**.

You can use **Shadows** only at module, namespace, or file level. This means you can declare shadowing variables in a source file or inside a module, class, or structure, but not inside a procedure. If you specify **Shadows**, you can optionally omit the **Dim** keyword.

You cannot specify both **Static** and **Shadows** in the same variable declaration.

ReadOnly

Optional. Variables declared with the **ReadOnly** keyword can only be read and not written. This can be useful for creating constant members of reference types, such as an object variable with preset data members.

You can use **ReadOnly** only at module, namespace, or file level. This means you can declare read-only variables in a source file or inside a module, class, or structure, but not inside a procedure. If you specify **ReadOnly**, you can optionally omit the **Dim** keyword.

WithEvents

Optional. Keyword that specifies that *name* is an object variable that refers to an instance of a class that can raise events. You can declare as many individual variables as you like using **WithEvents**, but you cannot declare arrays this way.

If you use the **WithEvents** keyword, you cannot declare *name* as **Object**. You must declare it as the specific class that can raise the events.

name

Required. Name of the variable. Must be a valid Visual Basic identifier. You can declare as many variables as you like in the same declaration statement, specifying the *name* part for each one and supplying the *boundlist* part for arrays. Multiple variables are separated by commas.

You can declare several variables to be of the same data type. You can also specify different types for different variables or groups of variables. Each variable takes the data type specified in the first **As** clause encountered after its *name* part.

boundlist

Optional. List of non-negative integers representing the upper bounds of the dimensions of an array variable. Multiple upper bounds are separated by commas. An array can have up to 60 dimensions.

Each value in *boundlist* specifies the upper bound of a dimension, not the length. The lower bound is always zero, so the subscript for each dimension can vary from zero through the upper-bound value.

It is possible to use -1 to declare the upper bound of an array dimension. This signifies that the array is empty but not **Nothing**, a distinction required by certain common language runtime functions. However, Visual Basic code cannot successfully access such an array. If you attempt to do so, an **IndexOutOfRangeException** error occurs during execution.

New

Optional. Keyword that enables immediate creation of an object. If you use **New** when declaring the object variable, a new instance of the object is created when the **Dim** statement is executed.

type

Optional unless **Option Strict** is **On**. Data type of the variable. Can be **Boolean**, **Byte**, **Char**, **Date**, **Decimal**, **Double**, **Integer**, **Long**, **Object**, **Short**, **Single**, or **String**; or the name of an enumeration, structure, class, or interface. You can use a separate **As** clause for each variable being defined, or you can define several variables to be of the same type by using a common **As** clause.

If you do not specify *type*, the variable takes the data type of *initexpr*. If you do specify *type*, the data type of *initexpr* must be convertible to *type*. If neither *type* nor *initexpr* is present, the data type defaults to **Object**.

initexpr

Optional. Expression that is evaluated and assigned to the variable when it is created. If you declare more than one variable with the same **As** clause, you cannot supply *initexpr* for that group of variables.

Each attribute in the *attrlist* part has the following syntax and parts:

```
attrname [({ attrargs | attrinit })]
```

***attrlist* Parts**

attrname
Required. Name of the attribute. Must be a valid Visual Basic identifier.
attrargs
Optional. List of positional arguments for this attribute. Multiple arguments are separated by commas.
attrinit
Optional. List of field or property initializers for this attribute. Multiple initializers are separated by commas.

Remarks

Variables declared with **Dim** are available to all code within the region containing the **Dim** statement. If they are declared in a module, class, or structure, but outside any procedure, they can be accessed from anywhere within that module, class, or structure. To specify their accessibility in more detail, include the **Public**, **Protected**, **Friend**, **Protected Friend**, or **Private** keywords.

```
Private TryCount As Integer
Protected Salary As Decimal
Friend ValidDate As Date
Public MaximumAllowed As Double
Protected Friend CurrentUserName As String
```

Variables declared inside a procedure or a block are accessible only from within that procedure or block. You cannot use any of the accessibility keywords for such variables. Their declaration statements must use either **Dim** or **Static**.

```
Dim Counter As Integer
Static TotalSales As Double
```

The **Dim** statement can declare the data type of a variable and initialize its contents. The declaration statements in the following example declare an **Integer** variable, a **Boolean** variable, and an object variable. These are initialized, respectively, to 10, **True**, and a newly created instance of the **Label** class in the **System.Windows.Forms** namespace.

```
Dim Quantity As Integer = 10
Dim FirstTry As Boolean = True
Dim MyLabel As New System.Windows.Forms.Label
```

If you do not specify an initialization value for a variable, Visual Basic initializes it to the default value for its data type. The default initialization values are as follows:

- 0 for all numeric types (including **Byte**).
- Binary 0 for **Char.**
- **Nothing** for all reference types (including **Object**, **String**, and all arrays).
- **False** for **Boolean.**
- 12:00 AM of January 1 of the year 1 for **Date.**

Each element of a structure or array is initialized as if it were a separate variable.

You can initialize the values of an array by surrounding the initialization values with braces (**{}**). The following example creates an array with four elements:

```
Dim A1() As Integer = {0, 1, 2, 3}
```

For multidimensional arrays, each separate dimension is surrounded with braces. The elements are specified in row-major order. The following example illustrates this:

```
' Initialize each array element to its row index + its column index.
Dim A2( , ) As Integer = {{0+0, 0+1, 0+2}, {1+0 ,1+1, 1+2}}
```

> **Note** You should put all your declaration statements at the beginning of the code region in which they appear, for example a module or a procedure. If a declaration statement initializes the value of a variable, it should be executed before any other statement makes reference to the variable.

A public variable can be either early bound or late bound. Protected, friend, and private variables cannot be late bound. This means you cannot access members on a late-bound object variable unless it is declared **Public**. If you attempt to do this, the compiler does not generate an error, but a **MissingMemberException** error occurs at run time.

A static variable has a longer lifetime than that of the procedure in which it is declared. The boundaries of the variable's lifetime depend on where the procedure is declared and whether or not it is **Shared**.

- If the procedure is declared in a module, its static variables are initialized the first time the procedure is called, and they continue to exist until your program terminates execution.
- If the procedure is declared as **Shared** within a class or structure, its static variables are initialized the first time the procedure is called either on a specific instance or on the class or structure itself. They remain in existence until the program terminates.
- If the procedure is declared within a class or structure and is not **Shared**, its static variables are associated with each individual instance of the class or structure. They are initialized the first time the procedure is called in that instance, and they continue to exist until that instance is released.

Example

This example uses the **Dim** statement to declare variables and arrays. The lower bound for array subscripts is always 0, and the upper bound is the value that appears in the **Dim** statement.

```
' Declarations do not have to initialize their variables.
' AnyValue and MyValue are initialized by default to Nothing.
Dim AnyValue, MyValue As Object
' Number is initialized by default to 0.
Dim Number As Integer
' Multiple declarations can be of the same data type or different types.
Dim FirstNumber, SecondNumber, ThirdNumber As Integer
Dim MyDate As Date, MyValue As Single, MySwitch As Boolean
' DayArray is an array of 51 Objects indexed from 0 through 50.
Dim DayArray(50) As Object
' Matrix2 is a two-dimensional array of type Integer.
Dim Matrix2(3, 4) As Integer
' Matrix3 is a three-dimensional array of type Double.
Dim Matrix3(5, 9, 5) As Double
' BirthDay is an array of 11 dates indexed from 0 through 10.
Dim BirthDay(10) As Date
' MyArray is an array of objects. The length of the array is assigned
' when another statement assigns an array object to MyArray.
Dim MyArray() As Object
```

See Also

Const Statement | ReDim Statement | Variable Declaration | Object Variables | Events and Delegates | Declaring Array Variables

Do...Loop Statements

Repeats a block of statements while a **Boolean** condition is **True** or until the condition becomes **True**.

```
Do { While | Until } condition
   [ statements ]
[ Exit Do ]
   [ statements ]
Loop
```

-or-

```
Do
   [ statements ]
[ Exit Do ]
   [ statements ]
Loop { While | Until } condition
```

Parts

While
Required unless **Until** is used. Keyword. Repeat the loop until *condition* is **False**.
Until
Required unless **While** is used. Keyword. Repeat the loop until *condition* is **True**.
condition
Optional. **Boolean**. Expression that evaluates to a value of **True** or **False**.
statements
Optional. One or more statements that are repeated while, or until, *condition* is **True**.

Remarks

The **Exit Do** statement transfers control immediately to the statement following the **Loop** statement. Any number of **Exit Do** statements can be placed anywhere in the **Do** loop. **Exit Do** is often used after evaluating some condition, for example with **If...Then...Else**.

Example

This example shows how **Do...Loop** statements can be used. The inner **Do...Loop** statement loops 10 times, sets the value of the flag to **False**, and exits prematurely using the **Exit Do** statement. The outer loop exits immediately upon checking the value of the flag.

```
Dim Check As Boolean = True
Dim Counter As Integer = 0
Do   ' Outer loop.
   Do While Counter < 20   ' Inner loop.
      Counter += 1   ' Increment Counter.
      If Counter = 10 Then   ' If condition is True,
         Check = False   ' Set value of flag to False.
         Exit Do   ' Exit inner loop.
      End If
   Loop
Loop Until Check = False   ' Exit outer loop immediately.
```

See Also

Exit Statement | For...Next Statements | Faster For...Next Loops | Do...Loop Statements (Conceptual) | While...End While Statements

End Statement

Terminates execution immediately.

```
End
```

Remarks

The **End** statement can be placed anywhere in a procedure to end code execution, close files opened with an **Open** statement, and clear variables. The **End** statement calls the **Exit** method of the **Environment** class in the **System** namespace. **System.Environment.Exit** requires that you have **SecurityPermissionFlag.UnmanagedCode** permissions. If you do not, a **SecurityException** error occurs.

When executed, the **End** statement clears all variables at module and class level and all static local variables in all modules.

> **Note** The **End** statement stops code execution abruptly, without invoking the **Finalize** method or any other Visual Basic code. Object references held by other programs are invalidated.

The **End** statement provides a way to force your program to halt. Your program closes as soon as there are no other programs holding references to its objects and none of its code is executing.

If your application has any forms open, you should close them before executing **End**. A console application can either use **End** or simply return from the **Main** procedure.

With an additional keyword, **End** delineates the end of the definition of the appropriate procedure or block.

Example

This example uses the **End** Statement to terminate code execution if the user requests it.

```
Sub Form_Load()
   ' ...
   Dim Answer As MsgBoxResult
   Answer = MsgBox("Do you want to quit now?", MsgBoxStyle.YesNo)
   If Answer = MsgBoxResult.Yes Then
      MsgBox("Terminating program")
      End
   End If
   ' ...
End Sub
```

Smart Device Developer Notes

This statement is not supported.

See Also

End | Requesting Minimum Permissions | SecurityPermissionFlag Enumeration

Enum Statement

Used at module, class, or structure level to declare an enumeration and define the values of its members.

```
[ <attrlist> ] [{ Public | Protected | Friend | Protected Friend |
Private }] [ Shadows ] Enum name [ As type ]
   [<attrlist1>] membname1 [ = initexpr1 ]
   [<attrlist2>] membname2 [ = initexpr2 ]
...
   [<attrlistn>] membnamen [ = initexprn ]
End Enum
```

Parts

attrlist
Optional. List of attributes that apply to the enumeration or to this member. Multiple attributes are separated by commas.

Public
Optional. Enumerations declared with the **Public** keyword have public access. There are no restrictions on the accessibility of public enumerations.

Protected
Optional. Enumerations declared with the **Protected** keyword have protected access. They are accessible only from within their own class or from a derived class. Protected access can be specified only on members of classes. It is not a superset of friend access.

Friend
Optional. Enumerations declared with the **Friend** keyword have friend access. They are accessible from within their declaration context and from anywhere else in the same program.

Protected Friend
Optional. Enumerations declared with the **Protected Friend** keywords have the union of protected and friend access. They can be used by code in the same program, as well as by code in derived classes. Protected friend access can be specified only on members of classes.

Private
Optional. Enumerations declared with the **Private** keyword have private access. They are accessible only from within their declaration context, including from members of any nested types such as procedures.

Shadows
Optional. Indicates that this enumeration shadows an identically named programming element, or set of overloaded elements, in a base class. You can shadow any kind of declared element with any other kind. A shadowed element is unavailable from within the derived class that shadows it, unless the shadowing element is inaccessible, for example if it is **Private**.

name
Required. Name of the enumeration. Must be a valid Visual Basic identifier. When you subsequently declare variables or arguments to be of this **Enum** type, you specify *name* for their data type.

type
Optional, even if **Option Strict** is **On**. Data type of the enumeration and all of its members. Can be **Byte**, **Integer**, **Long**, or **Short**. If you do not specify *type*, it defaults to **Integer**.

membname
Required. Name of this member of the enumeration. Must be a valid Visual Basic identifier.

The accessibility of every member is **Public**, and you cannot declare it otherwise. However, if the enumeration itself is declared with **Protected**, **Friend**, **Protected Friend**, or **Private** access, this limits the accessibility of the members.

initexpr
Optional. Expression that is evaluated and assigned to this member when the enumeration is created. Can consist of a literal; a constant that is already defined; another enumeration member; or any combination of literals, constants, and enumeration members. You can use arithmetic and logical operators to combine such elements.

You cannot use variables or functions in *initexpr*. However, you can use conversion keywords such as **CByte** and **CShort**. You can also use **AscW** if you call it with a constant **String** or **Char** argument, since that can be evaluated at compile time.

If you do not specify *initexpr*, the value assigned is either zero (if it is the first *membname*), or greater by one than the value of the immediately preceding *membname*.

End Enum
Terminates an **Enum** block.

Each attribute in the *attrlist* part has the following syntax and parts:

```
attrname [({ attrargs | attrinit })]
```

attrlist Parts

attrname
Required. Name of the attribute. Must be a valid Visual Basic identifier.
attrargs
Optional. List of positional arguments for this attribute. Multiple arguments are separated by commas.
attrinit
Optional. List of field or property initializers for this attribute. Multiple initializers are separated by commas.

Remarks

The **Enum** statement can appear only at module, namespace, or file level. This means you can declare enumerations in a source file or inside a module, class, or structure, but not inside a procedure. Once the **Enum** type is defined, it can be used to declare the type of variables, procedure arguments, and **Function** returns.

Enumerations can be accessed from anywhere within the module, class, or structure in which they are declared. An enumeration and all its members are **Public** by default. To specify the accessibility in more detail, include **Public**, **Protected**, **Friend**, **Protected Friend**, or **Private** in the **Enum** statement. The accessibility you specify applies to all the members as well as to the enumeration itself.

An enumeration is a related set of constants. The enumeration members between the **Enum** and **End Enum** statements are initialized to constant values. The defined values cannot be modified at run time. Values can include both positive and negative numbers, as the following example shows:

```
Enum SecurityLevel
   IllegalEntry = -1
   MinimumSecurity = 0
   MaximumSecurity = 1
End Enum
```

If the value of a member exceeds the allowable range for the underlying data type, or if you initialize any member to the maximum value allowed by the underlying data type, the compiler reports an error.

Enumeration variables are variables declared to be of an **Enum** type. Declaring a variable in this way helps you to control the values you assign to it. If **Option Strict** is **On**, you can assign only enumeration members to the enumeration variable. In this case, you can use the **CType** keyword to explicitly convert a numeric data type to an **Enum** type.

You must qualify every reference to an enumeration member, either with the name of an enumeration variable or with the enumeration name itself. For example, in the preceding example, you can refer to the first member as `SecurityLevel.IllegalEntry`, but not as `IllegalEntry`.

Example

This example uses the **Enum** statement to define a set of named constants. In this case, the constants are colors you might choose to design data entry forms for a database.

```
Public Enum InterfaceColors
   MistyRose   = &HE1E4FF&
   SlateGray   = &H908070&
   DodgerBlue  = &HFF901E&
   DeepSkyBlue = &HFFBF00&
   SpringGreen = &H7FFF00&
   ForestGreen = &H228B22&
   Goldenrod   = &H20A5DA&
   Firebrick   = &H2222B2&
End Enum
```

See Also

Erase Statement

Used to release array variables and deallocate the memory used for their elements.

```
Erase arraylist
```

Parts

arraylist
Required. List of array variables to be erased. Multiple variables are separated by commas.

Remarks

The **Erase** statement can appear only at procedure level. This means you can release arrays inside a procedure but not at class or module level.

The **Erase** statement is equivalent to assigning **Nothing** to each array variable.

Example

This example uses the **Erase** statement to clear two arrays and free their memory (1000 and 100 storage elements respectively). The **ReDim** statement then assigns a new array instance to the three-dimensional array.

```
Dim Int3DArray(9, 9, 9), Int2DArray(9, 9) As Integer
' ...
Erase Int3DArray, Int2DArray
' ...
ReDim Int3DArray(4, 4, 9)
```

See Also

Nothing | ReDim Statement

Error Statement

Simulates the occurrence of an error.

```
Error errornumber
```

Parts

errornumber
Required. Can be any valid error number.

Remarks

The **Error** statement is supported for backward compatibility. In new code, especially when creating objects, use the **Err** object's **Raise** method to generate run-time errors.

If *errornumber* is defined, the **Error** statement calls the error handler after the properties of the **Err** object are assigned the following default values:

Property	Value
Number	Value specified as argument to **Error** statement. Can be any valid error number.
Source	Name of the current Visual Basic project.
Description	String expression corresponding to the return value of the **Error** function for the specified **Number**, if this string exists. If the string doesn't exist, **Description** contains a zero-length string (").
HelpFile	The fully qualified drive, path, and file name of the appropriate Visual Basic Help file.
HelpContext	The appropriate Visual Basic Help file context ID for the error corresponding to the **Number** propert y.
LastDLLError	Zero.

If no error handler exists or if none is enabled, an error message is created and displayed from the **Err** object properties.

> **Note** Some Visual Basic host applications cannot create objects. See your host application's documentation to determine whether it can create classes and objects.

Example

This example uses the **Error** statement to generate error number 11.

```
On Error Resume Next   ' Defer error handling.
Error 11   ' Simulate the "Division by zero" error.
```

Requirements

Namespace: Microsoft.VisualBasic

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Declares a user-defined event.

```
[ <attrlist> ] [ Public | Private | Protected | Friend | Protected Friend ] _
[ Shadows ] Event eventname[(arglist)] _
[ Implements interfacename.interfaceeventname ]
```

Parts

attrlist
Optional. List of attributes that apply to this event. Multiple attributes are separated by commas.

Public
Optional. Entities declared with the **Public** modifier have public access. There are no restrictions on the use of public entities. Events that do not specify an access modifier are declared as **Public** by default.

Private
Optional. Entities declared with the **Private** modifier have private access. A private entity is accessible only within its declaration context, including any nested entities.

Protected
Optional. Entities declared with the **Protected** keyword have protected access. They are accessible only from within their own class or from a derived class. Protected access can be specified only on members of classes. It is not a superset of friend access.

Friend
Optional. Entities declared with the **Friend** modifier have friend access. An entity with friend access is accessible only within the program that contains the entity declaration.

Protected Friend
Optional. Entities declared with the **Protected Friend** modifiers have the union of protected and friend accessibility.

Shadows
Optional. Indicates that this event shadows an identically named programming element in a base class. You can shadow any kind of declared element with any other kind. A shadowed element is unavailable from within the derived class that shadows it, unless the shadowing element is inaccessible, for example if it is **Private**.

eventname
Required. Name of the event; follows standard variable naming conventions.

Implements
Optional. Indicates that this event implements an event of an interface.

interfacename
The name of an interface.

interfaceeventname
The name of the event being implemented.

Each attribute in the *attrlist* part has the following syntax and parts:

```
attrname [({ attrargs | attrinit })]
```

***attrlist* Parts**

attrname
Required. Name of the attribute. Must be a valid Visual Basic identifier.

attrargs
Optional. List of positional arguments for this attribute. Multiple arguments are separated by commas.

attrinit
Optional. List of field or property initializers for this attribute. Multiple initializers are separated by commas.

The *arglist* argument has the following syntax and parts:

```
[ <attrlist> ] [ ByVal | ByRef ] varname[ ( ) ] [ As type ]
```

***arglist* Parts**

attrlist

Optional. List of attributes that apply to this argument. Multiple attributes are separated by commas.

ByVal

Optional. Indicates that the argument is passed by value. **ByVal** is the default in Visual Basic.

ByRef

Optional. Indicates that the argument is passed by reference.

varname

Required. Name of the variable representing the argument being passed to the procedure; follows standard variable naming conventions.

type

Optional. Data type of the argument passed to the procedure; may be **Byte**, **Boolean**, **Char**, **Short**, **Integer**, **Long**, **Single**, **Double**, **Decimal**, **Date**, **String** (variable length only), **Object**, a user-defined type, or an object type.

Remarks

Once the event has been declared, use the **RaiseEvent** statement to raise the event. A typical event might be declared and raised as shown in the following fragments:

```
Public Class EventSource
   ' Declare an event.
   Public Event LogonCompleted(ByVal UserName As String)
   Sub CauseEvent()
      ' Raise an event on successful logon.
      RaiseEvent LogonCompleted("AustinSteele")
   End Sub
End Class
```

Note You can declare event arguments just as you do arguments of procedures, with the following exceptions: events cannot have named arguments, or **Optional** arguments. Events do not have return values.

Example

The following example uses events to count off seconds during a demonstration of the fastest 100-meter race. The code illustrates all of the event-related methods, properties, and statements, including the **RaiseEvent** statement.

The class that raises an event is the event source, and the methods that process the event are the event handlers. An event source can have multiple handlers for the events it generates. When the class raises the event, that event is raised on every class that has elected to handle events for that instance of the object.

The example also uses a form (`Form1`) with a button (`Command1`), a label (`Label1`), and two text boxes (`Text1` and `Text2`). When you click the button, the first text box displays "From Now" and the second starts to count seconds. When the full time (9.84 seconds) has elapsed, the first text box displays "Until Now" and the second displays "9.84"

The code for `Form1` specifies the initial and terminal states of the form. It also contains the code executed when events are raised.

To use this example, open a new Windows Forms project, add a button named `Button1`, a label named `Label1` and two text boxes, named `TextBox1` and `TextBox2`, to the main form, named `form1`. Then right click the form and click **View Code** to open the code editor.

To simplify access to the **Timer** property, add an **Imports** statement as the first line of code above the `Class Form1` statement.

```
Imports Microsoft.VisualBasic.DateAndTime
```

Add a **WithEvents** variable to the declarations section of the `Form1` class.

```
Private WithEvents mText As TimerState
```

Add the following code to the code for `Form1`. Replace any duplicate procedures that may exist, such as `Form_Load`, or `Button_Click`.

```
Private Sub Form1_Load(ByVal sender As Object, _
                       ByVal e As System.EventArgs) _
                       Handles MyBase.Load
   Button1.Text = "Click to Start Timer"
```

```
    TextBox1.Text = ""
    TextBox2.Text = ""
    Label1.Text = "The fastest 100 meters ever run took this long:"
    mText = New TimerState()
End Sub
Private Sub Button1_Click(ByVal sender As System.Object, _
                          ByVal e As System.EventArgs) _
                          Handles Button1.Click
    TextBox1.Text = "From Now"
    TextBox1.Refresh()
    TextBox2.Text = "0"
    TextBox2.Refresh()
    mText.TimerTask(9.84)
End Sub

Private Sub mText_ChangeText() Handles mText.ChangeText
    TextBox1.Text = "Until Now"
    TextBox2.Text = "9.84"
End Sub

Private Sub mText_UpdateTime(ByVal Jump As Double) _
       Handles mText.UpdateTime
    TextBox2.Text = Format(Jump, "##0.00")
    Application.DoEvents()
End Sub

Class TimerState
    Public Event UpdateTime(ByVal Jump As Double)
    Public Event ChangeText()
    Public Sub TimerTask(ByVal Duration As Double)
       Dim Start As Double
       Dim Second As Double
       Dim SoFar As Double
       Start = Timer
       SoFar = Start
       Do While Timer < Start + Duration
          If Timer - SoFar >= 0.1 Then
             SoFar = SoFar + 0.1
             RaiseEvent UpdateTime(Timer - Start)
          End If
       Loop
       RaiseEvent ChangeText()
    End Sub
End Class
```

Press F5 to run this example, and click the button labeled **Click to start timer**. The first text box displays "From Now" and the second starts to count seconds. When the full time (9.84 seconds) has elapsed, the first text box displays "Until Now" and the second displays "9.84".

RaiseEvent Statement | Implements Statement | Adding Events to a Class | Events and Delegates

Exit Statement

Exits a procedure or block and transfers control immediately to the statement following the procedure call or the block definition.

```
Exit { Do | For | Function | Property | Select | Sub | Try | While }
```

Parts

Do
Immediately exits the **Do** loop in which it appears. Execution continues with the statement following the **Loop** statement. **Exit Do** can be used only inside a **Do** loop. When used within nested **Do** loops, **Exit Do** transfers control to the loop that is one nested level above the loop where **Exit Do** occurs.

For
Immediately exits the **For** loop in which it appears. Execution continues with the statement following the **Next** statement. **Exit For** can be used only inside a **For...Next** or **For Each...Next** loop. When used within nested **For** loops, **Exit For** transfers control to the loop that is one nested level above the loop where **Exit For** occurs.

Function
Immediately exits the **Function** procedure in which it appears. Execution continues with the statement following the statement that called the **Function** procedure. **Exit Function** can be used only inside a **Function** procedure.

Property
Immediately exits the **Property** procedure in which it appears. Execution continues with the statement that called the **Property** procedure, that is, with the statement requesting or setting the property's value. **Exit Property** can be used only inside a **Property** procedure.

Select
Immediately exits the **Select Case** in which it appears. Execution continues with the statement following the **End Select** statement. **Exit Select** can be used only inside a **Select Case** statement.

Sub
Immediately exits the **Sub** procedure in which it appears. Execution continues with the statement following the statement that called the **Sub** procedure. **Exit Sub** can be used only inside a **Sub** procedure.

Try
Immediately exits the **Try** or **Catch** block in which it appears. Execution continues with the **Finally** block if there is one, or with the statement following the **End Try** statement otherwise. **Exit Try** can be used only inside a **Try...Catch...Finally** statement.

While
Immediately exits the **While** loop in which it appears. Execution continues with the statement following the **End While** statement. **Exit While** can be used only inside a **While** loop. When used within nested **While** loops, **Exit While** transfers control to the loop that is one nested level above the loop where **Exit While** occurs.

Remarks

Do not confuse **Exit** statements with **End** statements. **Exit** does not define the end of a statement.

Example

This example uses the **Exit** statement to exit a **For...Next** loop, a **Do...Loop**, and a **Sub** procedure.

```
Sub ExitStatementDemo()
Dim I, MyNum As Integer
   Do   ' Set up infinite loop.
      For I = 1 To 1000   ' Loop 1000 times.
         MyNum = Int(Rnd * 1000)   ' Generate random numbers.
         Select Case MyNum   ' Evaluate random number.
            Case 7: Exit For   ' If 7, exit For...Next.
            Case 29: Exit Do   ' If 29, exit Do...Loop.
            Case 54: Exit Sub   ' If 54, exit Sub procedure.
         End Select
      Next I
   Loop
End Sub
```

For Each...Next Statements

Repeats a group of statements for each element in a collection.

```
For Each element [ As datatype ] In group
   [ statements ]
[ Exit For ]
   [ statements ]
Next [ element ]
```

Parts

element
Required. Variable. Used to iterate through the elements of the collection. The data type of *element* must be such that the data type of the elements of *group* can be converted to it.

datatype
Required if *element* is not already declared. Data type of *element*. If *element* is declared outside this loop, you cannot use the **As** clause to redeclare it.

group
Required. Object variable. Must refer to an object collection or array.

statements
Optional. One or more statements between **For Each** and **Next** that are executed on each item in *group*.

Remarks

If *element* has not been declared outside this loop, you can declare it within the **For Each** statement. In this case, the scope of *element* is the body of the loop. However, you cannot declare *element* both outside and inside the loop.

The **For Each...Next** loop is entered if there is at least one element in *group*. Once the loop has been entered, the statements are executed for the first element in *group*; if there are more elements in *group*, the statements in the loop continue to execute for each element. When there are no more elements, the loop is terminated and execution continues with the statement following the **Next** statement.

Any number of **Exit For** statements may be placed anywhere in the loop as an alternative way to exit. **Exit For** is often used after evaluating some condition, for example with an **If...Then...Else** statement, and transfers control to the statement immediately following **Next**.

You can nest **For Each...Next** loops by placing one loop within another. Each loop must have a unique *element* variable.

Example

This example uses the **For Each...Next** statement to search the **Text** property of all elements in a collection for the existence of the string "Hello". In the example, `MyObject` is a text-related object and is an element of the collection `MyCollection`. Both are generic names used for illustration purposes only.

```
Dim Found As Boolean = False
Dim MyCollection As New Collection
For Each MyObject As Object In MyCollection   ' Iterate through elements.
   If CStr(MyObject.Text) = "Hello" Then   ' If Text equals "Hello"
      Found = True   ' Set Found to True.
      Exit For   ' Exit loop.
   End If
Next
```

For...Next Statements

Repeats a group of statements a specified number of times.

```
For counter [ As datatype ] = start To end [ Step step ]
   [ statements ]
[ Exit For ]
   [ statements ]
Next [ counter ]
```

Parts

counter
Required. Variable. The data type of *counter* is usually **Integer** but can be any elementary numeric type that supports the greater than or equal to (**>=**), less than or equal to (**<=**), and addition (**+**) operators.

datatype
Required if *counter* is not already declared. Data type of *counter*. If *counter* is declared outside this loop, you cannot use the **As** clause to redeclare it.

start
Required. Expression. The initial value of *counter*. The *start* expression usually evaluates to type **Integer** but can evaluate to any data type that widens to the type of *counter*.

end
Required. Expression. The final value of *counter*. The *end* expression usually evaluates to type **Integer** but can evaluate to any data type that widens to the type of *counter*.

step
Optional. Expression. The amount by which *counter* is incremented each time through the loop. The *step* expression usually evaluates to type **Integer** but can evaluate to any data type that widens to the type of *counter*. If not specified, *step* defaults to 1.

statements
Optional. One or more statements between **For** and **Next** that are executed the specified number of times.

Remarks

If *counter* has not been declared outside this loop, you can declare it within the **For** statement. In this case, the scope of *counter* is the body of the loop. However, you cannot declare *counter* both outside and inside the loop.

The *step* argument can be either positive or negative. The value of the *step* argument determines loop processing as follows:

Step value	Loop executes if
Positive or zero	*counter* <= *end*
Negative	*counter* >= *end*

The expressions *start*, *end*, and *step* are all evaluated only once, when the **For** statement is first encountered. They are not evaluated again, even if the loop statements change their constituent parts.

The *counter* variable is compared to *end* every time before the loop is entered. This includes the first time the **For** statement is executed. Therefore, if the value of *start* is past the value of *end* when the loop is entered, the loop is not executed, and execution passes immediately to the statement following the **Next** statement.

After the loop statements have executed, *step* is added to *counter*. At this point, the **For** statement again compares *counter* to *end*. As a result of this comparison, either the statements in the loop execute again, or the loop is terminated and execution continues with the statement following the **Next** statement.

Note Changing the value of *counter* while inside a loop can make it more difficult to read and debug your code.

The **Exit For** statement transfers control immediately to the statement following the **Next** statement. Any number of **Exit For** statements can be placed anywhere in the **For...Next** loop. **Exit For** is often used after evaluating some condition, for example with an **If...Then...Else** statement.

You can *nest* **For...Next** loops by placing one loop within another. Each loop must have a unique *counter* variable. The following construction is correct:

```
For I As Integer = 1 To 10
   For J As Integer = 1 To 10
```

```
      For K As Integer = 1 To 10
         ' Statements to operate with current values of I, J, and K.
      Next K
   Next J
Next I
```

Note If a **Next** statement is encountered before its corresponding **For** statement, or if a **Next** statement of an outer nesting level is encountered before the **Next** of an inner level, an error occurs.

Example

This example uses the **For...Next** statement to create a string that contains 10 instances of the numbers 0 through 9, each string separated from the other by a single space. The outer loop uses a loop counter variable that is decremented each time through the loop.

```
Dim Words, Digit As Integer
Dim MyString As String
For Words = 10 To 1 Step -1    ' Set up 10 repetitions.
   For Digit = 0 To 9   ' Set up 10 repetitions.
      MyString = MyString & CStr(Digit)   ' Append number to string.
   Next Digit   ' Increment counter.
   MyString = MyString & " "   ' Append a space.
Next Words
```

Function Statement

Declares the name, arguments, and code that define a **Function** procedure.

```
[ <attrlist> ] [{ Overloads | Overrides | Overridable |
NotOverridable | MustOverride | Shadows | Shared }]
[{ Public | Protected | Friend | Protected Friend | Private }]
Function name[(arglist)] [ As type ] [ Implements interface.definedname ]
   [ statements ]
   [ Exit Function ]
   [ statements ]
End Function
```

Parts

attrlist
Optional. List of attributes that apply to this procedure. Multiple attributes are separated by commas.

Overloads
Optional. Indicates that this **Function** procedure overloads one or more procedures defined with the same name in a base class. The argument list in this declaration must be different from the argument list of every overloaded procedure. The lists must differ in the number of arguments, their data types, or both. This allows the compiler to distinguish which version to use.

You do not have to use the **Overloads** keyword when you are defining multiple overloaded procedures in the same class. However, if you use **Overloads** in one of the declarations, you must use it in all of them.

You cannot specify both **Overloads** and **Shadows** in the same procedure declaration.

Overrides
Optional. Indicates that this **Function** procedure overrides an identically named procedure in a base class. The number and data types of the arguments, and the data type of the return value, must exactly match those of the base class procedure.

Overridable
Optional. Indicates that this **Function** procedure can be overridden by an identically named procedure in a derived class. **Overridable** is the default setting for a procedure that itself overrides a base class procedure.

NotOverridable
Optional. Indicates that this **Function** procedure cannot be overridden in a derived class. **NotOverridable** is the default setting for a procedure that does not itself override a base class procedure.

MustOverride
Optional. Indicates that this **Function** procedure is not implemented in this class, and must be implemented in a derived class for that class to be creatable.

Shadows
Optional. Indicates that this **Function** procedure shadows an identically named programming element, or set of overloaded elements, in a base class. You can shadow any kind of declared element with any other kind. If you shadow a procedure with another procedure, the arguments and the return type do not have to match those in the base class procedure. A shadowed element is unavailable from within the derived class that shadows it, unless the shadowing element is inaccessible, for example if it is **Private**.

You cannot specify both **Overloads** and **Shadows** in the same procedure declaration.

Shared
Optional. Indicates that this **Function** procedure is a shared procedure. This means it is not associated with a specific instance of a class or structure. You can call a shared procedure by qualifying it either with the class or structure name, or with the variable name of a specific instance of the class or structure.

Public
Optional. Procedures declared with the **Public** keyword have public access. There are no restrictions on the accessibility of public procedures.

Protected
Optional. Procedures declared with the **Protected** keyword have protected access. They are accessible only from within their own class or from a derived class. Protected access can be specified only on members of classes. It is not a superset of friend access.

Friend
Optional. Procedures declared with the **Friend** keyword have friend access. They are accessible from within their declaration context and from anywhere else in the same program.

Protected Friend
Optional. Procedures declared with the **Protected Friend** keywords have the union of protected and friend access. They can be used by code in the same program, as well as by code in derived classes. Protected friend access can be specified only on members of classes.

Private
Optional. Procedures declared with the **Private** keyword have private access. They are accessible only from within their declaration context, including from members of any nested types such as procedures.

name
Required. Name of the **Function** procedure. Must be a valid Visual Basic identifier.

arglist
Optional. List of variables or expressions representing arguments that are passed to the **Function** procedure when it is called. Multiple arguments are separated by commas. If you supply an argument list, you must enclose it in parentheses.

type
Optional unless **Option Strict** is **On**. Data type of the value returned by the **Function** procedure. Can be **Boolean**, **Byte**, **Char**, **Date**, **Decimal**, **Double**, **Integer**, **Long**, **Object**, **Short**, **Single**, or **String**; or the name of an enumeration, structure, class, or interface.

Implements
Optional. Indicates that this **Function** procedure implements a **Function** procedure defined by an interface.

interface
Required if **Implements** is supplied. The interface implemented by the class or structure containing this **Function** procedure. The class or structure must specify *interface* in an **Implements** statement immediately following the **Class** or **Structure** statement.

definedname
Required if **Implements** is supplied. The name by which the **Function** procedure is defined in *interface*. The name of this **Function** procedure (in *name*) does not have to be the same as *definedname*.

statements
Optional. A block of statements to be executed within the **Function** procedure.

End Function
Terminates the definition of this **Function** procedure.

Each argument in the *arglist* part has the following syntax and parts:

```
[ <attrlist> ] [ Optional ] [{ ByVal | ByRef }] [ ParamArray ]
argname[( )] [ As argtype ] [ = defaultvalue ]
```

***arglist* Parts**

attrlist
Optional. List of attributes that apply to this argument. Multiple attributes are separated by commas.

Optional
Optional. Indicates that this argument is not required when the procedure is called. If this keyword is used, all subsequent arguments in *arglist* must also be optional and be declared using the **Optional** keyword. Every optional argument declaration must supply the *defaultvalue* clause. **Optional** cannot be used for any argument if **ParamArray** is used.

ByVal
Optional. Indicates that the procedure cannot replace or reassign the underlying variable element in the calling code. However, if the argument is a reference type, the procedure can modify the contents or members of the underlying object. **ByVal** is the default in Visual Basic.

ByRef
Optional. Indicates that the procedure can modify the underlying variable in the calling code the same way the calling code itself can.

ParamArray
Optional. Used only as the last argument in *arglist* to indicate that the final argument is an optional array of elements of the specified type. The **ParamArray** keyword allows you to pass an arbitrary number of arguments to the procedure. A **ParamArray** argument is always passed using **ByVal**.

argname
Required. Name of the variable representing the argument. Must be a valid Visual Basic identifier.

argtype
Optional unless **Option Strict** is **On**. Data type of the argument passed to the procedure. Can be **Boolean**, **Byte**, **Char**, **Date**, **Decimal**, **Double**, **Integer**, **Long**, **Object**, **Short**, **Single**, or **String**; or the name of an enumeration, structure, class, or interface.

defaultvalue

Required for **Optional** arguments. Any constant or constant expression that evaluates to the data type of the argument. If the type is **Object**; or a class, interface, array, or structure, the default value can only be **Nothing**.

Each attribute in the *attrlist* part has the following syntax and parts:

```
attrname [({ attrargs | attrinit })]
```

attrlist Parts

attrname
Required. Name of the attribute. Must be a valid Visual Basic identifier.
attrargs
Optional. List of positional arguments for this attribute. Multiple arguments are separated by commas.
attrinit
Optional. List of field or property initializers for this attribute. Multiple initializers are separated by commas.

Remarks

All executable code must be in procedures. You can define a **Function** procedure inside a module, class, interface, or structure, but not inside another procedure.

Function procedures are **Public** by default. To specify a different accessibility, include **Protected**, **Friend**, **Protected Friend**, or **Private** in the declaration.

When the **Function** procedure returns to the calling program, execution continues with the statement following the statement that called it.

The **Exit Function** statement causes an immediate exit from a **Function** procedure. Any number of **Exit Function** statements can appear anywhere in the procedure.

To return a value from a function, you can either assign the value to the function name or include it in a **Return** statement. The following example assigns the return value to the function name `MyFunction` and then uses the **Exit Function** statement to return:

```
Function MyFunction(ByVal J As Integer) As Double
   ' ...
   MyFunction = 3.87
   ' ...
   Exit Function
   ' ...
End Function
```

If you use **Exit Function** without assigning a value to *name*, the function returns the default value appropriate to *argtype*. This is 0 for **Byte**, **Char**, **Decimal**, **Double**, **Integer**, **Long**, **Short**, and **Single**; **Nothing** for **Object**, **String**, and all arrays; **False** for **Boolean**; and #1/1/0001 12:00 AM# for **Date**.

The **Return** statement simultaneously assigns the return value and exits the function, as in the following example:

```
Function MyFunction(ByVal J As Integer) As Double
   ' ...
   Return 3.87
   ' ...
End Function
```

Any number of **Return** statements can appear anywhere in the procedure. You can also mix **Exit Function** and **Return** statements.

You can use a **Function** procedure on the right side of an expression when you want to use the value returned by the function. You use the **Function** procedure the same way you use any library function such as **Sqrt**, **Cos**, or **ChrW**.

You call a **Function** procedure by using the procedure name, followed by the argument list in parentheses, in an expression. You can omit the parentheses only if you are not supplying any arguments. A function can also be called using the **Call** statement, in which case the return value is ignored.

Note Visual Basic sometimes rearranges arithmetic expressions to increase internal efficiency. For that reason, avoid using a **Function** procedure in an arithmetic expression when the function changes the value of variables in the same expression.

Example

This example uses the **Function** statement to declare the name, arguments, and code that form the body of a **Function** procedure. The **ParamArray** keyword enables the function to accept a variable number of arguments.

```
Public Function CalcSum(ByVal ParamArray Args() As Double) As Double
   Dim I As Integer
   CalcSum = 0
   If Args.Length <= 0 Then Exit Function   ' No arguments passed.
   For I = 0 To UBound(Args, 1)
      CalcSum += Args(I)
   Next I
End Function   ' Returns latest value of CalcSum.
```

The function can be invoked as follows:

```
Dim ReturnedValue As Double
ReturnedValue = CalcSum(4, 3, 2, 1)
' The function's local variables are assigned the following values:
' Args(0) = 4, Args(1) = 3, and so on.
```

See Also

Call Statement | Sub Statement | Parameter Arrays | Dim Statement | Implements Statement

Get Statement

Declares a **Get** property procedure used to retrieve the value of a property.

```
[ <attrlist> ] Get()
   [ block ]
End Get
```

Parts

attrlist
Optional. List of attributes that apply to this **Get** block. Multiple attributes are separated by commas.
block
Optional. The body of the **Get** property procedure contains code to return the property value.
End Get
Terminates a **Get** property procedure.

Each attribute in the *attrlist* part has the following syntax and parts:

```
attrname [({ attrargs | attrinit })]
```

attrlist Parts

attrname
Required. Name of the attribute. Must be a valid Visual Basic identifier.
attrargs
Optional. List of positional arguments for this attribute. Multiple arguments are separated by commas.
attrinit
Optional. List of field or property initializers for this attribute. Multiple initializers are separated by commas.

Remarks

Get property procedures can return a value using either the **Return** keyword or by assigning the return value to the property where the get procedure is declared. The value returned by a **Get** property procedure is usually a private class level variable that stored the property value after a property set operation.

Example

This example uses the **Get** statement to return the value of a property.

```
Class PropClass
   ' Define a local variable to store the property value.
   Private CurrentTime As String
   ' Define the property.
   Public ReadOnly Property DateAndTime() As String
      Get
         ' Get procedure is called when the value
         ' of a property is retrieved.
         CurrentTime = CStr(Now)
         Return CurrentTime    ' Returns the date and time As a string.
      End Get
   End Property
End Class
```

See Also

Set Statement | Property Statement

GoTo Statement

Branches unconditionally to a specified line within a procedure.

```
GoTo line
```

Part

line
Required. Any line label.

Remarks

GoTo can branch only to lines within the procedure where it appears.

You cannot use a **GoTo** to branch from outside a **For...Next**, **For Each...Next**, **SyncLock...End SyncLock**, **Try...Catch...Finally**, or **With...End With** block to a label inside.

Within a **Try...Catch...Finally** construction, you cannot use **GoTo** to branch out of a **Try** block, into a **Catch** block, or into or out of a **Finally** block. You can branch from a **Catch** block into the **Try** block associated with that **Catch**. For example, if one **Try...Catch...Finally** construction is nested within another, a **Catch** block can branch into the **Try** block at its own nesting level, but not into any other **Try** block.

> **Note** **GoTo** statements can make code difficult to read and maintain. Whenever possible, use **Do...Loop**, **For...Next**, **If...Then...Else**, **Select Case**, **Try...Catch...Finally**, **While**, and **With...End With** structures instead.

Example

This example uses the **GoTo** statement to branch to line labels within a procedure.

```
Sub GotoStatementDemo()
Dim Number As Integer
dim MyString As String
   Number = 1   ' Initialize variable.
   ' Evaluate Number and branch to appropriate label.
   If Number = 1 Then GoTo Line1 Else GoTo Line2

Line1:
   MyString = "Number equals 1"
   GoTo LastLine   ' Go to LastLine.
Line2:
   ' The following statement never gets executed because Number = 1.
   MyString = "Number equals 2"
LastLine:
   ' Print "Number equals 1" in the Output window.
   Debug.WriteLine (MyString)
End Sub
```

See Also

Do...Loop Statements | For...Next Statements | If...Then...Else Statements | Select...Case Statements | Try...Catch...Finally Statements

If...Then...Else Statements

Conditionally executes a group of statements, depending on the value of an expression.

```
If condition [ Then ]
   [ statements  ]
[ ElseIf elseifcondition [ Then ]
   [ elseifstatements ] ]
[ Else
   [ elsestatements ] ]
End If
```

-or-

```
If condition Then [ statements ] [ Else elsestatements ]
```

Parts

condition
Required. Expression. The expression you supply for *condition* must evaluate to **True** or **False**, or to a data type that is implicitly convertible to **Boolean**.

statements
Optional in multiple-line form; required in single-line form that has no **Else** clause. One or more statements following **If...Then** that are executed if *condition* is **True**.

elseifcondition
Required if **ElseIf** is present. Same as *condition*.

elseifstatements
Optional. One or more statements following **ElseIf...Then** that are executed if the associated *elseifcondition* is **True**.

elsestatements
Optional in multiple-line form; required in single-line form that has an **Else** clause. One or more statements that are executed if no previous *condition* or *elseifcondition* expression is **True**.

End If
Terminates **If...Then** block.

Remarks

You can use the single-line form for short, simple tests. However, the multiple-line form provides more structure and flexibility than the single-line form and is usually easier to read, maintain, and debug.

With the single-line form, it is possible to have multiple statements executed as the result of an **If...Then** decision. All statements must be on the same line and be separated by colons, as in the following example:

```
If A > 10 Then A = A + 1 : B = B + A : C = C + B
```

In the multiple-line form, the **If** statement must be the only statement on the first line. The **Else**, **ElseIf**, and **End If** statements can be preceded only by a line label. The multiple-line **If...Then...Else** must end with an **End If** statement.

To determine whether or not an **If** statement introduces a multiple-line form, examine what follows the **Then** keyword. If anything other than a comment appears after **Then** in the same statement, the statement is treated as a single-line **If** statement. If **Then** is absent, it must be the beginning of a multiple-line **If...Then...Else**.

The **ElseIf** and **Else** clauses are both optional. You can have as many **ElseIf** clauses as you want in a multiple-line **If...Then...Else**, but none can appear after an **Else** clause. Multiple-line forms can be nested within one another.

When a multiple-line **If...Then...Else** is encountered, *condition* is tested. If *condition* is **True**, the statements following **Then** are executed. If *condition* is **False**, each **ElseIf** statement is evaluated in order. When a **True** *elseifcondition* is found, the statements immediately following the associated **Then** are executed. If no *elseifcondition* evaluates to **True**, or if there are no **ElseIf** statements, the statements following **Else** are executed. After executing the statements following **Then**, **ElseIf**, or **Else**, execution continues with the statement following **End If**.

Tip **Select Case** might be more useful when evaluating a single expression that has several possible values.

Example

This example shows both the multiple- and single-line forms of the **If...Then...Else** statement.

```
Dim Number, Digits As Integer
Dim MyString As String
Number = 53   ' Initialize variable.
If Number < 10 Then
   Digits = 1
ElseIf Number < 100 Then
' Condition evaluates to True so the next statement is executed.
   Digits = 2
Else
   Digits = 3
End If

' Assign a value using the single-line form of syntax.
If Digits = 1 Then MyString = "One" Else MyString = "More than one"
```

Use the **TypeOf** keyword to determine whether the **Control** object passed into a procedure is a text box.

```
Sub ControlProcessor(ByVal MyControl As Control)
   If TypeOf MyControl Is ComboBox Then
      Debug.WriteLine ("You passed in a " & TypeName(MyControl))
   ElseIf TypeOf MyControl Is CheckBox Then
      Debug.WriteLine ("You passed in a " & TypeName(MyControl))
   ElseIf TypeOf MyControl Is TextBox Then
      Debug.WriteLine ("You passed in a " & TypeName(MyControl))
   End If
End Sub
```

Implements Statement

Specifies one or more interfaces, or interface members, that will be implemented in the class or structure definition in which it appears.

```
Implements interfacename [, ...]
```

-or-

```
Implements interfacename.interfacemember [, ...]
```

Parts

interfacename
Required. An interface whose properties, methods, and events will be implemented by corresponding members in the class or structure.

interfacemember
Required. The member of an interface that is being implemented.

Remarks

An interface is a collection of prototypes representing the members (properties, methods and events) the interface encapsulates. Interfaces contain only the declarations for members; classes and structures implement these members.

When you implement an interface, you must implement all the members declared in the interface. Omitting any member is considered to be a syntax error. Classes can use **Private** implementations of properties and methods, but these members are only accessible by casting an instance of the implementing class into a variable declared to be of the type of the interface.

Example

The following example shows how to use the **Implements** statement to implement the properties, methods and events of an interface.

This example defines an interface named **ICustomerInfo** with a property, method, and an event. The Class **CustomerInfo** implements all the members defined in the interface.

```
Interface IcustomerInfo
' Declare an interface.
   Property CustomerName() As String
   Sub UpdateCustomerStatus()
   Event UpdateComplete()
End Interface

Public Class CustomerInfo
' The CustomerInfo class implements the IcustomerInfo interface.
   Implements ICustomerInfo
   Private CustomerNameValue As String ' Used to store the property value.
   Public Event UpdateComplete() Implements ICustomerInfo.UpdateComplete
   Public Property CustomerName() As String Implements _
      ICustomerInfo.CustomerName
      Get
         Return CustomerNameValue
      End Get
      Set(ByVal Value As String)
         ' The Value parameter is passed to the Set procedure
         ' when the contents of this property is modified.
         CustomerNameValue = Value ' Save the new value.
      End Set
   End Property
   Public Sub UpdateCustomerStatus() Implements _
      ICustomerInfo.UpdateCustomerStatus
      ' Add code here to update the status of this account.
```

```
        ' Raise an event to indicate that this method is done.
        RaiseEvent UpdateComplete()
    End Sub
End Class
```

The following two procedures show how you could use the implemented interface. To test the interface implementation, add these procedures to your project and call the `TestImplements` procedure.

```
Public Sub TestImplements()
'  This procedure tests the interface implementation by
'  creating an instance of the class that implements ICustomerInfo.
   Dim Cust As New CustomerInfo()
   ' Associate an event handler with the event
   ' that is raised by the Cust object.
   AddHandler Cust.UpdateComplete, AddressOf HandleUpdateComplete
   ' Set the CustomerName Property
   Cust.CustomerName = "Fred"
   ' Retrieve and display the CustomerName property.
   MsgBox("Customer name is: " & Cust.CustomerName)
   ' Call the update CustomerStatus method that
   ' raises the UpdateComplete event.
   Cust.UpdateCustomerStatus()
End Sub

Sub HandleUpdateComplete()
   ' This is the event handler for the UpdateComplete event.
   MsgBox("Update is complete.")
End Sub
```

Interface Statement | Interfaces in Visual Basic .NET | Polymorphism | How Visual Basic Provides Polymorphism

Imports Statement

Imports namespace names from referenced projects and assemblies. Also imports namespace names defined within the same project as the file in which the statement appears.

```
Imports [ aliasname = ] namespace
```

-or-

```
Imports [ aliasname = ] namespace.element
```

Parts

aliasname
Optional. The name by which *namespace* may also be known or referred to. When the **Imports** statement does not include *aliasname*, the elements defined within the specified *namespace* can be accessed within the file without qualification. When *aliasname* is specified, it must be used as a qualifier for the names contained in the namespace. Aliases are useful when you need to use items with the same name that are declared in one or more namespaces.

namespace
Required. The name of the namespace being imported. The namespace can be any number of nesting levels deep.

element
Optional. The name of an element declared in the namespace. The element can be an enumeration, structure, class, or module.

Remarks

Each file can contain any number of **Imports** statements. **Imports** statements must be placed before any declarations, including **Module** or **Class** statements, and before any references to identifiers.

The scope of the elements made available by an **Imports** statement depends on how specific you are when using the **Imports** statement. For example, if only a namespace is specified, all uniquely named members of that namespace, and members of modules within that namespace, are available without qualification. If both a namespace and the name of an element of that namespace are specified, only the members of that element are available without qualification.

It is not permitted to define a member at module level with the same name as an import alias.

Example

The following example imports the **Microsoft.VisualBasic.Strings** class and assigns an alias, `Str`, that can be used to access the **Left** method.

```
Imports Str = Microsoft.VisualBasic.Strings
' Place Imports statements at the top of your program
Class MyClass1
   Sub ShowHello()
      MsgBox(Str.Left("Hello World", 5)) ' Displays the word "Hello"
   End Sub
End Class
```

Introduction to the .NET Framework Class Library in Visual Studio | Namespace Statement | Namespaces | Visual Basic .NET and the .NET Framework

Inherits Statement

Causes the current class or interface to inherit the attributes, fields, properties, methods, and events from another class or interface.

```
Inherits typename
```

Parts

typename
Required. The name of a class or interface being inherited by the class or interface in which the **Inherits** statement is used.

Remarks

If used, the **Inherits** statement must be the first non-blank, non-comment line in a class definition.

An interface may inherit from more than one interface, but a class may only inherit from one other class.

Example

This example uses the **Inherits** statement to show how a class named `ThisClass` can inherit the fields, properties, methods and events from another class named `AnotherClass`.

```
Public Class ThisClass
   Inherits AnotherClass
   ' Add code to override, overload, or extend members
   ' inherited from the base class.
   ...' Variable, property, method, and event declarations here.
End Class
```

See Also

MustInherit | NotInheritable | MyBase | MyClass | Inheritance

Interface Statement

Declares the name of an interface, as well as the properties, methods and events that comprise the interface.

```
[ <attrlist> ] [ Public | Private | Protected | Friend | Protected Friend ] _
[ Shadows ] Interface name
   [ Inherits interfacename[, interfacename ]]
   [ [ Default ] Property proname ]
   [ Function memberame ]
   [ Sub memberame ]
   [ Event memberame ]
End Interface
```

Parts

attrlist
Optional. List of attributes that apply to this interface. Multiple attributes are separated by commas.

Public
Optional. Entities declared with the **Public** modifier have public access. There are no restrictions on the use of public entities.

Private
Optional. Entities declared with the **Private** modifier have private access. A private entity is accessible only within its declaration context, including any nested entities.

Protected
Optional. Entities declared with the **Protected** keyword have protected access. They are accessible only from within their own class or from a derived class. Protected access can be specified only on members of classes. It is not a superset of friend access.

Friend
Optional. Entities declared with the **Friend** modifier have friend access. An entity with friend access is accessible only within the program that contains the entity declaration. Interfaces that do not specify an access modifier are declared as **Friend** by default.

Protected Friend
Optional. Entities declared with the **Protected Friend** modifiers have the union of protected and friend accessibility.

Shadows
Optional. Indicates that this interface shadows an identically named programming element in a base class. You can shadow any kind of declared element with any other kind. A shadowed element is unavailable from within the derived class that shadows it, unless the shadowing element is inaccessible, for example if it is **Private**.

name
Required. Name of the interface; follows standard variable naming conventions.

Inherits
Optional. Specifies that the interface being declared inherits the properties and methods from the interface specified by *interfacename*.

interfacename
Required if optional **Inherits** statement is present. Indicates the name of one or more interfaces being inherited.

Default
Optional. Indicates that the property with which the **Default** keyword is associated is the default property for the interface.

Property
Optional. Indicates a **Property** procedure that is a member of the interface.

Function
Optional. Indicates a **Function** procedure that is a member of the interface.

Sub
Optional. Indicates a **Sub** procedure that is a member of the interface.

Event
Optional. Indicates an **Event** that is a member of the interface.

memberame
Required if optional **Property**, **Event**, **Function**, or **Sub** statements exist. Indicates the name of the property, procedure, or event.

End Interface
Terminates an **Interface** block.

Each attribute in the *attrlist* part has the following syntax and parts:

```
attrname [({ attrargs | attrinit })]
```

attrlist Parts

attrname
Required. Name of the attribute. Must be a valid Visual Basic identifier.
attrargs
Optional. List of positional arguments for this attribute. Multiple arguments are separated by commas.
attrinit
Optional. List of field or property initializers for this attribute. Multiple initializers are separated by commas.

Remarks

The methods and properties of an interface are implemented in a class. When methods are implemented, the return data type and the argument data types must exactly match those of the method described in the **Interface** block. The method name, however, need not be the same as that described in the **Interface** block. Methods being implemented in a class cannot be designated as **Shared,** nor can they be **Private**, except in a non-inheritable class.

The **Interface** statement can appear in the declaration section of any module. Interfaces are implicitly **Friend** by default but can be explicitly declared **Public**, **Friend**, **Protected**, **Protected Friend** or **Private**.

An interface can have, at most, one default property. This implies that an interface can either inherit only one interface containing a default property, or its definition block can contain one property that is marked as default.

An interface cannot inherit from another interface whose access level is more restrictive than its own. For example, a public interface cannot inherit a friend interface.

Example

This example uses the **Interface** statement to define a `MyInterface` interface, which must be implemented with a **Property** statement and a **Function** statement.

```
Public Interface MyInterface
   Property MyProp(ByVal MyStr As String)
   Function MyFunc(ByVal MyInt As Integer) As Integer
End Interface
```

See Also

Class Statement | Function Statement | Inherits Statement | Implements Statement | Interfaces in Visual Basic .NET | Sub Statement

Mid Statement

Replaces a specified number of characters in a **String** variable with characters from another string.

```
Mid( _
   ByRef Target As String, _
   ByVal Start As Integer, _
   Optional ByVal Length As Integer _
) = StringExpression
```

Parts

Target
Required. Name of the **String** variable to modify.
Start
Required. **Integer** expression. Character position in *Target* where the replacement of text begins. *Start* uses a one-based index.
Length
Optional. **Integer** expression. Number of characters to replace. If omitted, all of *String* is used.
StringExpression
Required. **String** expression that replaces part of *Target*.

Remarks

The number of characters replaced is always less than or equal to the number of characters in *Target*.

> **Note The MidB statement of earlier versions of Visual Basic replaces a substring in bytes, rather than characters. It is used primarily for converting strings in double-byte character set (DBCS) applications. All Visual Basic .NET strings are in Unicode, and MidB is no longer supported**.

Example

This example uses the **Mid** statement to replace a specified number of characters in a string variable with characters from another string.

```
Dim MyString As String
MyString = "The dog jumps"   ' Initializes string.
Mid(MyString, 5, 3) = "fox"   ' MyString = "The fox jumps".
Mid(MyString, 5) = "cow"   ' MyString = "The cow jumps".
Mid(MyString, 5) = "cow jumped over"   ' MyString = "The cow jumpe".
Mid(MyString, 5, 3) = "duck"   ' MyString = "The duc jumpe".
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Strings

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Strings | String Manipulation | Mid Function

Module Statement

Declares a module block.

```
[ <attrilist> ] [ Public | Friend ] Module name
   [ statements ]
End Module
```

Parts

attrlist
Optional. List of attributes that apply to this module. Multiple attributes are separated by commas.

Public
Optional. Modules declared with the **Public** keyword have public access. There are no restrictions on the accessibility of public modules.

Friend
Optional. Modules declared with the **Friend** keyword have friend access. They are accessible from within their declaration context and from anywhere else in the same program. Modules that do not specify an access modifier are declared as **Friend** by default.

name
Required. Name of the module. Must be a valid Visual Basic identifier.

statements
Optional. Statements that comprise the variables, properties, events, and methods of the module.

End Module
Terminates a **Module** block.

Each attribute in the *attrlist* part has the following syntax and parts:

```
attrname [({ attrargs | attrinit })]
```

attrlist Parts

attrname
Required. Name of the attribute. Must be a valid Visual Basic identifier.

attrargs
Optional. List of positional arguments for this attribute. Multiple arguments are separated by commas.

attrinit
Optional. List of field or property initializers for this attribute. Multiple initializers are separated by commas.

Remarks

Modules are a reference type similar to classes, but with some important distinctions. The members of a module are implicitly **Shared** and scoped to the declaration space of the standard module's containing namespace, rather than just to the module itself. Unlike classes, modules can never be instantiated, do not support inheritance, and cannot implement interfaces. A module can only be declared in a namespace and cannot be nested in another type.

You can have multiple modules in a project, but members with the same name defined in two or more modules must be qualified with their module name when accessed outside of their module.

Example

```
Public Module Module1
   ' Add classes, properties, methods, fields, and events for this module.
End Module
```

See Also

Class Statement | Namespace Statement | Property Statement

Namespace Statement

Declares the name of a namespace.

```
Namespace { name | name.name }
   [ componenttypes ]
End Namespace
```

Parts

name
Required. A unique name that identifies the namespace.

componenttypes
Optional. Elements that make up the namespace. These include (but are not limited to) enumerations, structures, interfaces, classes, modules, delegates, and other namespaces.

End Namespace
Terminates a **Namespace** block.

Remarks

Namespaces are used as an organizational system - a way of presenting program components that are exposed to other programs and applications.

Namespaces are always **Public;** therefore the declaration of a namespace cannot include access modifiers. However, the components within the namespace may have **Public** or **Friend** access. If it is not stated, the default access type is **Friend**.

Example

The following example declares two namespaces.

```
Namespace N1   ' Declares a namespace named N1.
   Namespace N2   ' Declares a namespace named N2 within N1.
      Class A   ' Declares a class within N1.N2.
      ' Add class statements here.
      End Class
   End Namespace
End Namespace
```

The next example declares multiple nested namespaces on a single line, and is equivalent to the previous example.

```
Namespace N1.N2 ' Declares two namespaces; N1 and N2.
   Class A   ' Declares a class within N1.N2.
      ' Add class statements here.
   End Class
End Namespace
```

See Also

Imports Statement | Namespaces

On Error Statement

Enables an error-handling routine and specifies the location of the routine within a procedure; can also be used to disable an error-handling routine. Without an **On Error** statement, any run-time error that occurs is fatal: an error message is displayed, and execution stops.

```
On Error { GoTo [ line | 0 | -1 ] | Resume Next }
```

Parts

GoTo *line*
Enables the error-handling routine that starts at the line specified in the required *line* argument. The *line* argument is any line label or line number. If a run-time error occurs, control branches to the specified line, making the error handler active. The specified line must be in the same procedure as the **On Error** statement, or a compile-time error will occur.

GoTo 0
Disables enabled error handler in the current procedure and resets it to **Nothing**.

GoTo -1
Disables enabled exception in the current procedure and resets it to **Nothing**.

Resume Next
Specifies that when a run-time error occurs, control goes to the statement immediately following the statement where the error occurred and execution continues from that point. Use this form rather than **On Error GoTo** when accessing objects.

Remarks

An "enabled" error handler is one that is turned on by an **On Error** statement; an "active" error handler is an enabled handler that is in the process of handling an error. If an error occurs while an error handler is active (between the occurrence of the error and a **Resume**, **Exit Sub**, **Exit Function**, or **Exit Property** statement), the current procedure's error handler can't handle the error. Control returns to the calling procedure. If the calling procedure has an enabled error handler, it is activated to handle the error. If the calling procedure's error handler is also active, control passes back through previous calling procedures until an enabled, but inactive, error handler is found. If no such error handler is found, the error is fatal at the point at which it actually occurred.

Each time the error handler passes control back to a calling procedure, that procedure becomes the current procedure. Once an error is handled by an error handler in any procedure, execution resumes in the current procedure at the point designated by the **Resume** statement.

> **Note** An error-handling routine is not a **Sub** procedure or a **Function** procedure. It is a section of code marked by a line label or a line number.

Error-handling routines rely on the value in the **Number** property of the **Err** object to determine the cause of the error. The routine should test or save relevant property values in the **Err** object before any other error can occur or before a procedure that might cause an error is called. The property values in the **Err** object reflect only the most recent error. The error message associated with **Err.Number** is contained in **Err.Description**.

An error that is raised with the **Err.Raise** method will set the **Exception** property to a newly created instance of the **Exception** class. In order to support the raising of exceptions of derived exception types, a **Throw** statement is supported in the language. This takes a single parameter that is the exception instance to be thrown. The following example shows how these features can be used with the existing exception handling support:

```
    On Error GoTo Handler
    Throw New DivideByZeroException()
Handler:
    If (TypeOf Err.GetException() Is DivideByZeroException) Then
    ' Code for handling the error is entered here.
    End If
```

Note that the **On Error GoTo** statement traps all errors regardless of the exception class.

On Error Resume Next causes execution to continue with the statement immediately following the statement that caused the run-time error, or with the statement immediately following the most recent call out of the procedure containing the **On Error Resume Next** statement. This statement allows execution to continue despite a run-time error. You can place the error-handling routine where the error would occur rather than transferring control to another location within the procedure. An **On Error**

Resume Next statement becomes inactive when another procedure is called, so you should execute an **On Error Resume Next** statement in each called routine if you want inline error handling within that routine.

> **Note** The **On Error Resume Next** construct may be preferable to **On Error GoTo** when handling errors generated during access to other objects. Checking **Err** after each interaction with an object removes ambiguity about which object was accessed by the code. You can be sure which object placed the error code in **Err.Number**, as well as which object originally generated the error (the object specified in **Err.Source**).

On Error GoTo 0 disables error handling in the current procedure. It doesn't specify line 0 as the start of the error-handling code, even if the procedure contains a line numbered 0. Without an **On Error GoTo 0** statement, an error handler is automatically disabled when a procedure is exited.

On Error GoTo -1 disables the exception in the current procedure. It doesn't specify line -1 as the start of the error-handling code, even if the procedure contains a line numbered -1. Without an **On Error GoTo -1** statement, an exception is automatically disabled when a procedure is exited.

To prevent error-handling code from running when no error has occurred, place an **Exit Sub**, **Exit Function**, or **Exit Property** statement immediately before the error-handling routine, as in the following fragment:

```
Public Sub InitializeMatrix(Var1, Var2, Var3, Var4)
   On Error GoTo ErrorHandler
   ' Insert code that might generate an error here
   Exit Sub
ErrorHandler:
   ' Insert code to handle the error here
   Resume Next
End Sub
```

Here, the error-handling code follows the **Exit Sub** statement and precedes the **End Sub** statement to separate it from the procedure flow. You can place error-handling code anywhere in a procedure.

Untrapped errors in objects are returned to the controlling application when the object is running as an executable file. Within the development environment, untrapped errors are returned to the controlling application only if the proper options are set. See your host application's documentation for a description of which options should be set during debugging, how to set them, and whether the host can create classes.

If you create an object that accesses other objects, you should try to handle any unhandled errors they pass back. If you cannot, map the error codes in **Err.Number** to one of your own errors and then pass them back to the caller of your object. You should specify your error by adding your error code to the **VbObjectError** constant. For example, if your error code is 1052, assign it as follows:

```
Err.Number = VbObjectError + 1052
```

> **Caution** System errors during calls to Windows dynamic-link libraries (DLL) do not raise exceptions and cannot be trapped with Visual Basic error trapping. When calling DLL functions, you should check each return value for success or failure (according to the API specifications), and in the event of a failure, check the value in the **Err** object's **LastDLLError** property.

Example

This example first uses the **On Error GoTo** statement to specify the location of an error-handling routine within a procedure. In the example, an attempt to divide by zero generates error number 6. The error is handled in the error-handling routine, and control is then returned to the statement that caused the error. The **On Error GoTo 0** statement turns off error trapping. Then the **On Error Resume Next** statement is used to defer error trapping so that the context for the error generated by the next statement can be known for certain. Note that **Err.Clear** is used to clear the **Err** object's properties after the error is handled.

```
Public Sub OnErrorDemo()
   On Error GoTo ErrorHandler   ' Enable error-handling routine.
   Dim x As Integer = 32
   Dim y As Integer = 0
   Dim z As Integer
   z = x / y   ' Creates a divide by zero error
   On Error GoTo 0   ' Turn off error trapping.
   On Error Resume Next   ' Defer error trapping.
```

```
    z = x / y   ' Creates a divide by zero error again
    If Err.Number = 6 Then
       ' Tell user what happened. Then clear the Err object.
       Dim Msg As String
       Msg = "There was an error attempting to divide by zero!"
       MsgBox(Msg, , "Divide by zero error")
       Err.Clear() ' Clear Err object fields.
    End If
 Exit Sub      ' Exit to avoid handler.
 ErrorHandler:  ' Error-handling routine.
    Select Case Err.Number   ' Evaluate error number.
       Case 6   ' Divide by zero error
          MsgBox("You attempted to divide by zero!")
          ' Insert code to handle this error
       Case Else
          ' Insert code to handle other situations here...
    End Select
    Resume Next  ' Resume execution at same line
                 ' that caused the error.
 End Sub
```

Requirements

Namespace: Microsoft.VisualBasic

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

End Statement | Err Object | Exit Statement | LastDLLError Property | Resume Statement | Visual Basic Run-Time Errors

Option Compare Statement

Used at file level to declare the default comparison method to use when string data is compared.

```
Option Compare { Binary | Text }
```

Parts

Binary
Optional. Results in string comparisons based on a sort order derived from the internal binary representations of the characters.

Text
Optional. Results in string comparisons based on a case-insensitive text sort order determined by your system's locale.

Remarks

If used, the **Option Compare** statement must appear in a file before any other source statements.

The **Option Compare** statement specifies the string comparison method (**Binary** or **Text**) for a class, module or structure. If an **Option Compare** statement is not included, the default text comparison method is **Binary**.

In Microsoft Windows, sort order is determined by the code page. In the following example, characters are sorted using **Option Compare Binary**, which produces a typical binary sort order:

```
A < B < E < Z < a < b < e < z < À < Ê < Ø < à < ê < ø
```

When the same characters are sorted using **Option Compare Text**, the following text sort order is produced:

```
(A=a) < (À = à) < (B=b) < (E=e) < (Ê = ê) < (Z=z) < (Ø = ø)
```

Example

This example uses the **Option Compare** statement to set the default string comparison method. The **Option Compare** statement is used at the module level only.

```
' Set the string comparison method to Binary.
Option Compare Binary   ' That is, "AAA" is less than "aaa".
' Set the string comparison method to Text.
Option Compare Text   ' That is, "AAA" is equal to "aaa".
```

See Also

Comparison Operators | InStr Function | InStrRev Function | Option Strict Statement | Option Explicit Statement | Replace Function | Split Function | StrComp Function | /optionexplicit | /optionstrict | /optioncompare:binary | /optioncompare:text

Option Explicit Statement

Used at file level to force explicit declaration of all variables in that file.

```
Option Explicit { On | Off }
```

Parts

On
Optional. Enables **Option Explicit** checking. If **On** or **Off** is not specified after the **Option Explicit** statement, the default is **On**.

Off
Optional. Disables **Option Explicit** checking.

Remarks

If used, the **Option Explicit** statement must appear in a file before any other source statements.

When **Option Explicit** appears in a file, you must explicitly declare all variables using the **Dim**, **Private**, **Public**, or **ReDim** statements. If you attempt to use an undeclared variable name, an error occurs at compile time.

If you don't use the **Option Explicit** statement, all undeclared variables are of **Object** type.

> **Note** Use **Option Explicit** to avoid incorrectly typing the name of an existing variable or to avoid confusion in code where the scope of the variable is not clear. If you do not specify **Option Explicit** in your code, the compiler default is **Option Explicit On**.

Example

This example uses the **Option Explicit** statement to force explicit declaration of all variables. Attempting to use an undeclared variable causes an error at compile time. The **Option Explicit** statement is used at the module level only.

```
Option Explicit On   ' Force explicit variable declaration.
Dim MyVar As Integer   ' Declare variable.
MyInt = 10   ' Undeclared variable generates error.
MyVar = 10   ' Declared variable does not generate error.
```

See Also

Const Statement | Dim Statement | Function Statement | Option Compare Statement | Private | Public | ReDim Statement | Sub Statement | /optionexplicit | /optionstrict | /optioncompare:binary | /optioncompare:text

Option Strict Statement

Restricts implicit data type conversions to only *widening* conversions. This explicitly disallows any data type conversions in which data loss would occur and any conversion between numeric types and strings.

```
Option Strict { On | Off }
```

Parts

On
Optional. Enables **Option Strict** checking. If **On** or **Off** is not specified after the **Option Strict** statement, the default is **On**.

Off
Optional. Disables **Option Strict** checking.

Remarks

When used, the **Option Strict** statement must appear before any other code.

Visual Basic .NET generally allows implicit conversions of any data type to any other data type. Data loss can occur when the value of one data type is converted to a data type with less precision or smaller capacity, however, a run-time error message will occur if data will be lost in such a conversion. **Option Strict** ensures compile-time notification of these types of conversions so they may be avoided.

In addition to disallowing narrowing conversions, **Option Strict** generates an error for *late binding*. An object is late bound when it is assigned to a variable that is declared to be of type Object.

> **Note** The compiler default is **Option Strict Off** if do not specify **Option Strict** in your code.

Example

This example demonstrates how the **Option Strict** statement disallows late binding and conversions where data would be lost.

```
Option Strict On   ' Force explicit variable declaration.

Dim MyVar As Integer   ' Declare variables.
Dim Obj As Object

MyVar = 1000   ' Declared variable does not generate error.

'Attempting to convert to an Integer generates an error.
MyVar = 1234567890.987654321
'
'Call Obj.Method1()   ' Late-bound call generates an error
```

Property Statement

Declares the name of a property, and the property procedures used to store and retrieve the value of the property.

```
[ <attrlist> ] [ Default ] [ Public | Private | Protected | Friend | Protected Friend ] _
[[ ReadOnly | WriteOnly ] [ Overloads | Overrides ] _
[ Overridable | NotOverridable ] | MustOverride | Shadows | Shared ] _
Property varname([ ByVal parameter list ]) [ As typename ] [ Implements interfacemember ]
   [ <attrlist> ] Get
      [ block ]
   End Get
   [ <attrlist> ] Set(ByVal value As typename )
      [ block ]
   End Set
End Property
```

Parts

attrlist
Optional. List of attributes that apply to this property. Multiple attributes are separated by commas.

Default
Optional. Declares a default property. Default properties must accept parameters and can be set and retrieved without specifying the property name.

Overloads
Optional. Indicates that this property overloads one or more properties defined with the same name in a base class. The argument list in this declaration must be different from the argument list of every overloaded property. The lists must differ in the number of arguments, their data types, or both. This allows the compiler to distinguish which version to use.

You do not have to use the **Overloads** keyword when you are defining multiple overloaded properties in the same class. However, if you use **Overloads** in one of the declarations, you must use it in all of them.

You cannot specify both **Overloads** and **Shadows** in the same property declaration.

Overrides
Optional. Indicates that this property overrides an identically named property in a base class. The number and data types of the arguments, and the data type of the return value, must exactly match those of the base class property.

Overridable
Optional. Indicates that this property can be overridden by an identically named property in a derived class.

NotOverridable
Optional. Indicates that this property cannot be overridden in a derived class. Properties are **NotOverridable** by default but you cannot specify the **NotOverridable** modifier with properties or methods that do not override another member.

MustOverride
Optional. Indicates that this property is not implemented in this class, and must be implemented in a derived class for that class to be creatable.

Shadows
Optional. Indicates that this property shadows an identically named programming element, or set of overloaded elements, in a base class. You can shadow any kind of declared element with any other kind. If you shadow a property with another property, the arguments and the return type do not have to match those in the base class property. A shadowed element is unavailable from within the derived class that shadows it, unless the shadowing element is inaccessible, for example if it is **Private**.

> **Note** You cannot specify both **Overloads** and **Shadows** in the same property declaration.

Shared
Optional. Indicates that this is a shared property. This means it is not associated with a specific instance of a class or structure. You can call a shared property by qualifying it either with the class or structure name, or with the variable name of a specific instance of the class or structure.

Public
Optional. Entities declared with the **Public** modifier have public access. There are no restrictions on the use of public entities. Properties that do not specify an access modifier are **Public** by default.

Private
Optional. Entities declared with the **Private** modifier have private access. A private entity is accessible only within its declaration context, including any nested entities.

Protected
Optional. Entities declared with the **Protected** keyword have protected access. They are accessible only from within their own class or from a derived class. Protected access can be specified only on members of classes. It is not a superset of friend access.
Friend
Optional. Entities declared with the **Friend** modifier have friend access. An entity with friend access is accessible only within the program that contains the entity declaration.
Protected Friend
Optional. Entities declared with the **Protected Friend** modifiers have the union of protected and friend accessibility.
ReadOnly
Optional. Indicates that a property's value can be retrieved, but it cannot be modified. **ReadOnly** properties contain **Get** blocks but lack **Set** blocks.
WriteOnly
Optional. Indicates that a property can be the target of assignment but its value cannot be retrieved. **WriteOnly** properties contain **Set** blocks but lack **Get** blocks.
varname
Required. A unique name that identifies the property.
parameter list
Optional. This identifies the signature of the property. Parameters for properties must be passed **ByVal**.
typename
Optional. If no data type is specified, the default type is **Object**. If the property is implementing a property in an interface, *typename* must match the type declared in the interface.
Implements
Optional. Indicates that this property implements a property of an interface.
interfacemember
Optional. When a property is part of a class that implements an interface, this is the name of the property being implemented.
Get
Starts a **Get** property procedure used to return the value of a property. **Get** blocks are required unless the property is marked **WriteOnly**.
End Get
Terminates a **Get** property procedure.
Set
Starts a **Set** property procedure used to set the value of a property. **Set** blocks are required unless the property is marked **ReadOnly**. The new value of a property is passed to the **Set** property procedure in a parameter named *value* when the value of the property changes
End Set
Terminates a **Set** property procedure.
End Property
Terminates a **Property** definition.

Each attribute in the *attrlist* part has the following syntax and parts:

```
attrname [({ attrargs | attrinit })]
```

***attrlist* Parts**

attrname
Required. Name of the attribute. Must be a valid Visual Basic identifier.
attrargs
Optional. List of positional arguments for this attribute. Multiple arguments are separated by commas.
attrinit
Optional. List of field or property initializers for this attribute. Multiple initializers are separated by commas.

Remarks

Visual Basic .NET passes a parameter to the **Set** block during property assignments. If you do not supply a parameter for **Set**, the integrated development environment (IDE) supplies a parameter named **Value**. The parameter contains the contents of the item that was assigned to the property when the Set block was called. The contents of the parameter are usually stored in a private local variable and returned whenever the **Get** block is called.

The declaration of the property determines what the user can do with that property:

- If the **ReadOnly** modifier is used, the property is known as a "Read-only property" and must only have a **Get...End Get**

block. Therefore, the user is only able to retrieve the value of the property. An error will be raised if the user attempts to assign a value to that property.

- If the **WriteOnly** modifier is used, the property is known as a "Write-only property" and must only have a **Set...End Set** block. This allows the user to store a value to the property. An error will be raised if the user attempts to refer to the property, except in the assignment of a value to that property.
- If neither the **ReadOnly** nor the **WriteOnly** modifier is used, the property must have both a **Set...End Set** and a **Get...End Get** block. The property is said to be a read-write property.

Example

The following example declares a property in a class.

```
Class Class1
   ' Define a local variable to store the property value.
   Private PropertyValue As String
   ' Define the property.
   Public Property Prop1() As String
      Get
         ' The Get property procedure is called when the value
         ' of a property is retrieved.
         Return PropertyValue
      End Get
      Set(ByVal Value As String)
         ' The Set property procedure is called when the value
         ' of a property is modified.
         ' The value to be assigned is passed in the argument to Set.
         PropertyValue = Value
      End Set
   End Property
End Class
```

Q-Z Statements

The following table contains a listing of the Visual Basic .NET language statements.

RaiseEvent	Randomize	ReDim	REM
RemoveHandler	Resume	Return	Select Case
Set	Stop	Structure	Sub
SyncLock	Throw	Try...Catch...Finally	While...End While
With...End With			

See Also

A-E Statements | F-P Statements | Visual Basic Language and Run-Time Reference

RaiseEvent Statement

Triggers an event declared at module level within a class, form, or document.

```
RaiseEvent eventname[( argumentlist )]
```

The required *eventname* is the name of an event declared within the module. It follows Visual Basic variable naming conventions.

Parts

eventname
Required. Name of the event to trigger.
argumentlist
Optional. Comma-delimited list of variables, arrays, or expressions. The *argumentlist* argument must be enclosed by parentheses. If there are no arguments, the parentheses must be omitted.

Remarks

If the event has not been declared within the module in which it is raised, an error occurs. The following fragment illustrates an event declaration and a procedure in which the event is raised.

```
' Declare an event at module level.
Event LogonCompleted(UserName As String)

Sub Logon(ByVal UserName As String)
   ' Raise the event.
   RaiseEvent LogonCompleted(UserName)
End Sub
```

You cannot use **RaiseEvent** to raise events that are not explicitly declared in the module. For example, if a form has a Click event, you cannot raise its Click event using **RaiseEvent**. If you declare a Click event in the form module, it shadows the form's own Click event. You can still invoke the form's Click event using normal syntax for calling the event, but not using the **RaiseEvent** statement.

Events are raised in the order that the connections are established. Since events can have **ByRef** parameters, a process that connects late may receive parameters that have been changed by an earlier event handler.

> **Note** Non-shared events should not be raised within the constructor of the class in which they are declared. Although such events do not cause runtime errors, they may fail to be caught by associated event handlers. Use the **Shared** keyword to create a shared event if you need to raise an event from a constructor.

Example

The following example uses events to count off seconds during a demonstration of the fastest 100-meter race. The code illustrates all of the event-related methods, properties, and statements, including the **RaiseEvent** statement.

The class that raises an event is the event source, and the methods that process the event are the event handlers. An event source can have multiple handlers for the events it generates. When the class raises the event, that event is raised on every class that has elected to handle events for that instance of the object.

The example also uses a form (`Form1`) with a button (`Command1`), a label (`Label1`), and two text boxes (`Text1` and `Text2`). When you click the button, the first text box displays "From Now" and the second starts to count seconds. When the full time (9.84 seconds) has elapsed, the first text box displays "Until Now" and the second displays "9.84"

The code for `Form1` specifies the initial and terminal states of the form. It also contains the code executed when events are raised.

To use this example, open a new Windows Forms project, add a button named `Button1`, a label named `Label1` and two text boxes, named `TextBox1` and `TextBox2`, to the main form, named `form1`. Then right click the form and click **View Code** to open the code editor.

To simplify access to the Timer property, add an **Imports** statement as the first line of code above the `Class Form1` statement.

```
Imports Microsoft.VisualBasic.DateAndTime
```

Add a **WithEvents** variable to the declarations section of the `Form1` class.

```
Private WithEvents mText As TimerState
```

Add the following code to the code for `Form1`. Replace any duplicate procedures that may exist, such as `Form_Load`, or `Button_Click`.

```
Private Sub Form1_Load(ByVal sender As Object, _
                       ByVal e As System.EventArgs) _
                       Handles MyBase.Load
   Button1.Text = "Click to Start Timer"
   TextBox1.Text = ""
   TextBox2.Text = ""
   Label1.Text = "The fastest 100 meters ever run took this long:"
   mText = New TimerState()
End Sub
Private Sub Button1_Click(ByVal sender As System.Object, _
                          ByVal e As System.EventArgs) _
                          Handles Button1.Click
   TextBox1.Text = "From Now"
   TextBox1.Refresh()
   TextBox2.Text = "0"
   TextBox2.Refresh()
   mText.TimerTask(9.84)
End Sub

Private Sub mText_ChangeText() Handles mText.ChangeText
   TextBox1.Text = "Until Now"
   TextBox2.Text = "9.84"
End Sub

Private Sub mText_UpdateTime(ByVal Jump As Double) _
      Handles mText.UpdateTime
   TextBox2.Text = Format(Jump, "##0.00")
   Application.DoEvents()
End Sub

Class TimerState
   Public Event UpdateTime(ByVal Jump As Double)
   Public Event ChangeText()
   Public Sub TimerTask(ByVal Duration As Double)
      Dim Start As Double
      Dim Second As Double
      Dim SoFar As Double
      Start = Timer
      SoFar = Start
      Do While Timer < Start + Duration
         If Timer - SoFar >= 0.1 Then
            SoFar = SoFar + 0.1
            RaiseEvent UpdateTime(Timer - Start)
         End If
      Loop
      RaiseEvent ChangeText()
   End Sub
End Class
```

Press F5 to run this example, and click the button labeled **Click to start timer**. The text box will count up to 9.84 seconds.

Events and Delegates | Adding Events to a Class | Event Statement

Randomize Statement

Initializes the random-number generator.

```
Public Shared Sub Randomize [ number ]
```

Part

number
Optional. An **Object** or any valid numeric expression.

Remarks

Randomize uses *number* to initialize the **Rnd** function's random-number generator, giving it a new seed value. If you omit *number*, the value returned by the system timer is used as the new seed value.

If **Randomize** is not used, the **Rnd** function (with no arguments) uses the same number as a seed the first time it is called, and thereafter uses the last-generated number as a seed value.

> **Note** To repeat sequences of random numbers, call **Rnd** with a negative argument immediately before using **Randomize** with a numeric argument. Using **Randomize** with the same value for *number* does not repeat the previous sequence.
>
> **Security Note** Because the **Random** statement and the **Rnd** function start with a seed value and generate numbers that fall within a finite range, the results may be predictable by someone who knows the algorithm used to generate them. Consequently, the **Random** statement and the **Rnd** function should not be used to generate random numbers for use in cryptography.

Example

This example uses the **Randomize** statement to initialize the random-number generator. Because the number argument has been omitted, **Randomize** uses the return value from the **Timer** function as the new seed value.

```
Dim MyValue As Integer
Randomize   ' Initialize random-number generator.
MyValue = CInt(Int((6 * Rnd()) + 1)) ' Generate random value between 1 and 6.
```

Requirements

Namespace: Microsoft.VisualBasic

Module: VBMath

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

Rnd Function

ReDim Statement

Used at procedure level to reallocate storage space for an array variable.

```
ReDim [ Preserve ] name(boundlist)
```

Parts

Preserve
Optional. Keyword used to preserve the data in the existing array when you change the size of only the last dimension.

name
Required. Name of the variable. Must be a valid Visual Basic identifier. You can redimension as many variables as you like in the same statement, specifying the *name* and *boundlist* parts for each one. Multiple variables are separated by commas.

boundlist
Required. List of non-negative integers representing the upper bounds of the dimensions of the redefined array. Multiple upper bounds are separated by commas. The number of dimensions in *boundlist* must match the original rank of the array.

Each value in *boundlist* specifies the upper bound of a dimension, not the length. The lower bound is always zero, so the subscript for each dimension can vary from zero through the upper bound.

It is possible to use -1 to declare the upper bound of an array dimension. This signifies that the array is empty but not **Nothing**, a distinction required by certain common language runtime functions. However, Visual Basic code cannot successfully access such an array. If you attempt to do so, an **IndexOutOfRangeException** error occurs during execution.

Remarks

The **ReDim** statement can appear only at procedure level. This means you can redefine arrays inside a procedure but not at class or module level.

The **ReDim** statement is used to change the size of one or more dimensions of an array that has already been formally declared. **ReDim** cannot change the rank (the number of dimensions) of the array.

The **ReDim** statement cannot change the data type of an array variable or provide new initialization values for the array elements.

ReDim releases the existing array and creates a new array with the same rank. The elements of the new array are initialized to the default value for their data type unless you specify **Preserve**.

If you include the **Preserve** keyword, Visual Basic copies the elements from the existing array to the new array. When you use **Preserve**, you can resize only the last dimension of the array, and for every other dimension you must specify the same size it already has in the existing array.

For example, if your array has only one dimension, you can resize that dimension and still preserve the contents of the array, because it is the last and only dimension. However, if your array has two or more dimensions, you can change the size of only the last dimension if you use **Preserve**.

The following example increases the size of the last dimension of a dynamic array without losing any existing data in the array, and then decreases the size with partial data loss:

```
Dim IntArray(10, 10, 10) As Integer
' ...
ReDim Preserve IntArray(10, 10, 20)
' ...
ReDim Preserve IntArray(10, 10, 15)
```

The first **ReDim** creates a new array, copying all the elements from the existing array. It also adds 10 more columns to the end of every row in every layer. The elements in these new columns are initialized to the default value of the element type of the array.

The second **ReDim** creates another new array, copying all the elements that fit. However, five columns are lost from the end of every row in every layer. This is not a problem if you have finished using these columns. Reducing the size of a large array can free up memory that you no longer need.

You can use **ReDim** on a property that holds an array of values.

Example

This example uses the **ReDim** statement to allocate and reallocate storage space for array variables.

```
Dim I, MyArray() As Integer   ' Declare variable and array variable.
ReDim MyArray(5) ' Allocate 6 elements.
For I = 0 To UBound(MyArray)
   MyArray(I) = I   ' Initialize array.
Next I
```

The next statement resizes the array without saving the contents of the elements.

```
ReDim MyArray(10) ' Resize to 11 elements.
For I = 0 To UBound(MyArray)
   MyArray(I) = I   ' Initialize array.
Next I
```

The following statement resizes the array but saves the contents of the elements.

```
ReDim Preserve MyArray(15) ' Resize to 16 elements.
```

See Also

Const Statement | Dim Statement | Erase Statement

REM Statement

Used to include explanatory remarks in a program.

```
REM comment
```

-or-

```
' comment
```

Parts

comment
Optional. The text of any comment you want to include. A space is required between the **REM** keyword and *comment*.

Remarks

You can put a **REM** statement alone on a line, or you can put it on a line following another statement. The **REM** statement must be the last statement on the line. If it follows another statement, the **REM** must be separated from that statement by a space.

You can use a single quote (') instead of **REM**. This is true whether your comment follows another statement on the same line or sits alone on a line.

> **Note** You cannot continue a **REM** statement by using a line-continuation sequence (_). Once a comment begins, the compiler does not examine the characters for special meaning. For a multiple-line comment, use another **REM** statement or a comment symbol (') on each line.

Example

This example illustrates the **REM** statement, which is used to include explanatory remarks in a program. It also shows the alternative of using the single quote character (') instead of **REM**.

```
Dim MyStr1, MyStr2 as String
MyStr1 = "Hello" REM Comment after a statement using REM.
MyStr2 = "Goodbye"   ' Comment after a statement using the ' character.
REM This entire line is a comment.
' This entire line is also a comment.
```

Comments in Code

RemoveHandler Statement

Removes the association between an event and an event handler.

```
RemoveHandler event, AddressOf eventhandler
```

Parts

event
The name of the event being handled.
eventhandler
The name of the procedure currently handling the event.

Remarks

The **AddHandler** and **RemoveHandler** statements allow you to start and stop event handling for a specific event at any time during program execution.

Example

```
Sub TestEvents()
   Dim Obj As New Class1()
   ' Associate an event handler with an event.
   AddHandler Obj.Ev_Event, AddressOf EventHandler
   Obj.CauseSomeEvent() ' Ask the object to raise an event.
   RemoveHandler Obj.Ev_Event, AddressOf EventHandler ' Stop handling events.
   Obj.CauseSomeEvent() ' This event will not be handled.
End Sub

   Sub EventHandler()
      MsgBox("EventHandler caught event.") ' Handle the event.
   End Sub

Public Class Class1
   Public Event Ev_Event()  ' Declare an event.
   Sub CauseSomeEvent()
      RaiseEvent Ev_Event() ' Raise an event.
   End Sub
End Class
```

See Also

AddHandler Statement | Handles | Events and Event Handlers | AddHandler and RemoveHandler

Resume Statement

Resumes execution after an error-handling routine is finished.

```
Resume [ Next | line ]
```

Parts

Resume
Required. If the error occurred in the same procedure as the error handler, execution resumes with the statement that caused the error. If the error occurred in a called procedure, execution resumes at the statement that last called out of the procedure containing the error-handling routine.

Next
Optional. If the error occurred in the same procedure as the error handler, execution resumes with the statement immediately following the statement that caused the error. If the error occurred in a called procedure, execution resumes with the statement immediately following the statement that last called out of the procedure containing the error-handling routine (or **On Error Resume Next** statement).

line
Optional. Execution resumes at the line specified in the required *line* argument. The *line* argument is a line label or line number and must be in the same procedure as the error handler.

Remarks

If you use a **Resume** statement anywhere except in an error-handling routine, an error will occur.

The **Resume** statement cannot be used in any procedure that contains a **Try...Catch...Finally** statement.

Example

This example uses the **Resume** statement to end error handling in a procedure, and then resume execution with the statement that caused the error. Error number 55 is generated to illustrate using the **Resume** statement.

```
Sub ResumeStatementDemo()
   On Error GoTo ErrorHandler   ' Enable error-handling routine.
   Dim x As Integer = 32
   Dim y As Integer = 0
   Dim z As Integer
   z = x / y   ' Creates a divide by zero error
   Exit Sub   ' Exit Sub to avoid error handler.
ErrorHandler:   ' Error-handling routine.
   Select Case Err.Number   ' Evaluate error number.
      Case 6   ' "Divide by zero" error.
         y = 1 ' Sets the value of y to 1 and tries the calculation again.
      Case Else
         ' Handle other situations here....
   End Select
   Resume   ' Resume execution at same line
   ' that caused the error.
End Sub
```

Requirements

Namespace: Microsoft.VisualBasic

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Try...Catch...Finally Statements | Error Statement | On Error Statement

Return Statement

Returns control to the code that called a **Sub**, **Function**, or **Property** procedure.

```
Return
```

-or-

```
Return expr
```

Part

expr
Required in a **Function** procedure or a **Property** procedure that retrieves the property's value. An expression that represents the value to be returned to the calling code.

Remarks

For a **Sub** procedure or a **Property** procedure that sets the property's value, the **Return** statement is equivalent to an **Exit Sub** statement, and *expr* must not be supplied.

For a **Function** procedure or a **Property** procedure that retrieves the property's value, *expr* must be present and must evaluate to a data type that is convertible to the return type of the function. In this form, **Return** is equivalent to assigning the expression to the function name as the return value and then executing an **Exit Function** statement.

Example

This example uses the **Return** statement several times to return to the calling code when the procedure does not need to do anything else.

```
Public Function GetAgePhrase(Age As Integer) As String
   If Age > 60 Then Return "Senior"
   If Age > 40 Then Return "Middle-aged"
   If Age > 20 Then Return "Adult"
   If Age > 12 Then Return "Teen-aged"
   If Age > 4 Then Return "School-aged"
   If Age > 1 Then Return "Toddler"
   Return "Infant"
End Function
```

See Also

Function Statement | Sub Statement

Select...Case Statements

Executes one of several groups of statements, depending on the value of an expression.

```
Select [ Case ] testexpression
   [ Case expressionlist
      [ statements ] ]
   [ Case Else
      [ elsestatements ] ]
End Select
```

Parts

testexpression
Required. Expression. Must evaluate to one of the elementary data types (**Boolean**, **Byte**, **Char**, **Date**, **Double**, **Decimal**, **Integer**, **Long**, **Object**, **Short**, **Single**, and **String**).

expressionlist
Required in a **Case** statement. List of expression clauses representing match values for *testexpression*. Multiple expression clauses are separated by commas. Each clause can take one of the following forms:

- *expression1* **To** *expression2*
- [**Is**] *comparisonoperator expression*
- *expression*

Use the **To** keyword to specify the boundaries of a range of match values for *testexpression*. The value of *expression1* must be less than or equal to the value of *expression2*.

Use the **Is** keyword with a comparison operator (**=**, **<>**, **<**, **<=**, **>**, or **>=**) to specify a restriction on the match values for *testexpression*. If the **Is** keyword is not supplied, it is automatically inserted before *comparisonoperator*.

The form specifying only *expression* is treated as a special case of the **Is** form where *comparisonoperator* is the equal sign (**=**). This form is evaluated as *testexpression* = *expression*.

The expressions in *expressionlist* can be of any data type, provided they are implicitly convertible to the type of *testexpression* and the appropriate *comparisonoperator* is valid for the two types it is being used with.

statements
Optional. One or more statements following **Case** that are executed if *testexpression* matches any clause in *expressionlist*.

elsestatements
Optional. One or more statements following **Case Else** that are executed if *testexpression* does not match any clause in the *expressionlist* of any of the **Case** statements.

End Select
Terminates **Select...Case** block.

Remarks

If *testexpression* matches any **Case** *expressionlist* clause, the statements following that **Case** statement are executed up to the next **Case** statement or the **End Select** statement. Control then passes to the statement following **End Select**. If *testexpression* matches an *expressionlist* clause in more than one **Case** clause, only the statements following the first match are executed.

The **Case Else** statement is used to introduce the *elsestatements* to be executed if no match is found between the *testexpression* and an *expressionlist* clause in any of the other **Case** statements. Although not required, it is a good idea to have a **Case Else** statement in your **Select Case** block to handle unforeseen *testexpression* values. If no **Case** *expressionlist* clause matches *testexpression* and there is no **Case Else** statement, execution continues at the statement following **End Select**.

You can use multiple expressions or ranges in each **Case** clause. For example, the following line is valid:

```
Case 1 To 4, 7 To 9, 11, 13, Is > MaxNumber
```

Note The **Is** keyword used in the **Case** and **Case Else** statements is not the same as the **Is** comparison operator.

You also can specify ranges and multiple expressions for character strings. In the following example, **Case** matches strings that

are exactly equal to "apples", strings with values between "nuts" and "soup" in alphabetical order, and the current value of `TestItem`:

```
Case "apples", "nuts" To "soup", TestItem
```

The setting of **Option Compare** can affect string comparisons. Under **Option Compare Text**, the strings "Apples" and "apples" compare as equal, but under **Option Compare Binary**, they do not.

Select Case statements can be nested. Each nested **Select Case** statement must have a matching **End Select** statement.

If you do not need to execute any more of the statements in a **Case** or **Case Else** statement block, you can exit the block by using the **Exit Select** statement. This transfers control immediately to the statement following **End Select**.

Example

This example uses the **Select Case** statements to write a line corresponding to the value of the variable `Number`. The second **Case** statement contains the value that matches the current value of `Number`, so the statement that writes "Between 6 and 8" is executed.

```
Dim Number As Integer = 8
' ...
Select Number   ' Evaluate Number.
   Case 1 To 5   ' Number between 1 and 5, inclusive.
      Debug.WriteLine("Between 1 and 5")
   ' The following is the only Case clause that evaluates to True.
   Case 6, 7, 8   ' Number between 6 and 8.
      Debug.WriteLine("Between 6 and 8")
   Case 9 To 10   ' Number is 9 or 10.
      Debug.WriteLine("Greater than 8")
   Case Else   ' Other values.
      Debug.WriteLine("Not between 1 and 10")
End Select
```

Choose Function | End Statement | If...Then...Else Statements | Select...Case Statements (Conceptual) | Option Compare Statement | Exit Statement

Set Statement

Declares a **Set** property procedure used to assign a value to a property.

```
[ <attrlist> ] Set(ByVal value [ As datatype ])
   [ block ]
End Set
```

Parts

attrlist
Optional. List of attributes that apply to this **Set** block. Multiple attributes are separated by commas.
value
Required. This parameter contains the new value for the property.
datatype
Required if **Option Strict** is **On**. Declares the data type of the value parameter. The data type specified must be the same as the data type of the property where this **Set** statement is declared.
block
Optional. The body of the **Set** procedure contains code to set the property value.
End Set
Terminates a **Set** property procedure.

Each attribute in the *attrlist* part has the following syntax and parts:

```
attrname [({ attrargs | attrinit })]
```

attrlist Parts

attrname
Required. Name of the attribute. Must be a valid Visual Basic identifier.
attrargs
Optional. List of positional arguments for this attribute. Multiple arguments are separated by commas.
attrinit
Optional. List of field or property initializers for this attribute. Multiple initializers are separated by commas.

Remarks

Visual Basic .NET calls the **Set** property procedure when the value of a property is changed in an assignment operation.

Example

This example uses the **Set** statement to set the value of a property.

```
Class PropClass
   Private PropVal As Integer
   Property Prop1() As Integer
      Get
         Return PropVal ' Same As Prop1 = PropVal
      End Get
      Set(ByVal Value As Integer)
         PropVal = Value
      End Set
   End Property
End Class
```

See Also

Get Statement | Property Statement | Adding Fields and Properties to a Class

Stop Statement

Suspends execution.

```
Stop
```

Remarks

You can place **Stop** statements anywhere in procedures to suspend execution. Using the **Stop** statement is similar to setting a breakpoint in the code.

The **Stop** statement suspends execution, but unlike **End**, it does not close any files or clear any variables, unless it is encountered in a compiled executable (.exe) file.

> **Note** If the **Stop** statement is encountered in code that is running outside of the integrated development environment (IDE), the debugger is invoked. This is true regardless of whether the code was compiled in debug or retail mode.

Example

This example uses the **Stop** statement to suspend execution for each iteration through the **For...Next** loop.

```
Dim I As Integer
For I = 1 To 10   ' Start For...Next loop.
   Debug.WriteLine (I)   ' Print I to the Output window.
   Stop   ' Stop during each iteration and wait for user to resume.
Next I
```

See Also

End Statement

Structure Statement

Used at module or class level to declare a structure and define the characteristics of its members.

```
[ <attrlist> ] [{ Public | Protected | Friend | Protected Friend | Private }] [ Shadows ]
Structure name
   [ Implements interfacenames ]
   variabledeclarations
   [ proceduredeclarations ]
End Structure
```

Parts

attrlist
Optional. List of attributes that apply to this structure. Multiple attributes are separated by commas.

Public
Optional. Structures declared with the **Public** keyword have public access. There are no restrictions on the accessibility of public structures.

Protected
Optional. Structures declared with the **Protected** keyword have protected access. They are accessible only from within their own class or from a derived class. Protected access can be specified only on members of classes. It is not a superset of friend access.

Friend
Optional. Structures declared with the **Friend** keyword have friend access. They are accessible from within their declaration context and from anywhere else in the same program.

Protected Friend
Optional. Structures declared with the **Protected Friend** modifiers have the union of protected and friend access. They can be used by code in the same program, as well as by code in derived classes. Protected friend access can be specified only on members of classes.

Private
Optional. Structures declared with the **Private** modifier have private access. They are accessible only from within their declaration context, including from members of any nested types such as procedures.

Shadows
Optional. Indicates that this structure shadows an identically named programming element, or set of overloaded elements, in a base class. You can shadow any kind of declared element with any other kind. A shadowed element is unavailable from within the derived class that shadows it, unless the shadowing element is inaccessible, for example if it is **Private**.

name
Required. Name of the structure. Must be a valid Visual Basic identifier.

Implements
Optional. Indicates that this structure implements the members of one or more interfaces.

interfacenames
Required if the **Implements** statement is used. The names of the interfaces implemented by this structure. If you use the **Implements** statement, it must immediately follow the **Structure** statement, and you must implement every member defined by every interface you specify.

variabledeclarations
Required. One or more **Dim**, **Event**, **Friend**, **Private**, or **Public** statements declaring variables and events that serve as data members of the structure. These declarations follow the same rules as they do outside of a structure.

You can also define constants and properties in the structure, but you must declare at least one nonshared variable or event.

proceduredeclarations
Optional. Zero or more declarations of **Function**, **Property**, or **Sub** procedures that serve as method members of the structure. These declarations follow the same rules as they do outside of a structure.

Each attribute in the *attrlist* part has the following syntax and parts:

```
attrname [({ attrargs | attrinit })]
```

***attrlist* Parts**

attrname
Required. Name of the attribute. Must be a valid Visual Basic identifier.
attrargs
Optional. List of positional arguments for this attribute. Multiple arguments are separated by commas.
attrinit
Optional. List of field or property initializers for this attribute. Multiple initializers are separated by commas.

Remarks

The **Structure** statement can appear only at module, namespace, or file level. This means you can declare structures in a source file or inside a module, interface, or class, but not inside a procedure. You can also define one structure inside another, but you cannot access its members through the outer structure. Instead, you must declare a variable of the inner structure's data type.

Structures can be accessed from anywhere within the module or class in which they are declared. A structure is **Friend** by default. To specify the accessibility in more detail, include **Public**, **Protected**, **Friend**, **Protected Friend**, or **Private** in the **Structure** statement.

You must declare every data member of a structure. This means every statement in the *variabledeclarations* part must use **Dim**, **Friend**, **Private**, or **Public**. A structure member cannot be **Protected** or **Protected Friend** because nothing can inherit from a structure. The structure itself, however, can be **Protected** or **Protected Friend**.

If **Option Strict** is **On**, you must also include the **As** clause in every member declaration. Members declared with **Dim** default to **Public** access, and members declared without the **As** clause default to the **Object** data type.

You must define at least one nonshared variable or event in a structure. You cannot have only constants, properties, and procedures, even if some of them are nonshared.

The scope of every structure member is the entire structure.

You cannot initialize the value of any data member of a structure as part of its declaration. You must either initialize a data member by means of a parameterized constructor on the structure, or assign a value to the member after you have created an instance of the structure.

Structures support many of the same features as classes. For example, structures can have properties and methods, they can implement interfaces, and they can have parameterized constructors. However, there are significant differences between structures and classes in areas such as inheritance, declarations, and usage.

Example

This example uses the **Structure** statement to define a set of related data for an employee. It shows the use of **Public**, **Friend**, and **Private** members to reflect the sensitivity of the data items. It also shows procedure, property, and event members.

```
Public Structure Employee
   ' Public members, accessible throughout declaration region.
   Public FirstName As String
   Public MiddleName As String
   Public LastName As String
   ' Friend members, accessible anywhere within the same program.
   Friend EmployeeNumber As Integer
   Friend WorkPhone As Long
   ' Private members, accessible only within the structure itself.
   Private HomePhone As Long
   Private Level As Integer
   Private Salary As Double
   Private Bonus As Double
   ' Procedure member, which can access structure's private members.
   Friend Sub CalculateBonus(ByVal Rate As Single)
      Bonus = Salary * CDbl(Rate)
   End Sub
   ' Property member to return employee's eligibility.
   Friend ReadOnly Property Eligible() As Boolean
      Get
         Return Level >= 25
      End Get
   End Property
   ' Event member, raised when business phone number has changed.
   Public Event ChangedWorkPhone(ByVal NewPhone As Long)
```

```
End Structure
```

See Also

Dim Statement | Implements Statement | Structures and Classes | Event Statement | Property Statement

Sub Statement

Declares the name, arguments, and code that define a **Sub** procedure.

```
[ <attrlist> ] [{ Overloads | Overrides | Overridable |
NotOverridable | MustOverride | Shadows | Shared }]
[{ Public | Protected | Friend | Protected Friend | Private }]
Sub name [(arglist)] [ Implements interface.definedname ]
   [ statements ]
   [ Exit Sub ]
   [ statements ]
End Sub
```

Parts

attrlist
Optional. List of attributes that apply to this procedure. Multiple attributes are separated by commas.

Overloads
Optional. Indicates that this **Sub** procedure overloads one or more procedures defined with the same name in a base class. The argument list in this declaration must be different from the argument list of every overloaded procedure. The lists must differ in the number of arguments, their data types, or both. This allows the compiler to distinguish which version to use.

You do not have to use the **Overloads** keyword when you are defining multiple overloaded procedures in the same class. However, if you use **Overloads** in one of the declarations, you must use it in all of them.

You cannot specify both **Overloads** and **Shadows** in the same procedure declaration.

Overrides
Optional. Indicates that this **Sub** procedure overrides an identically named procedure in a base class. The number and data types of the arguments must exactly match those of the base class procedure.

Overridable
Optional. Indicates that this **Sub** procedure can be overridden by an identically named procedure in a derived class. **Overridable** is the default setting for a procedure that itself overrides a base class procedure.

NotOverridable
Optional. Indicates that this **Sub** procedure cannot be overridden in a derived class. **NotOverridable** is the default setting for a procedure that does not itself override a base class procedure.

MustOverride
Optional. Indicates that this **Sub** procedure is not implemented in this class and must be implemented in a derived class for that class to be creatable.

Shadows
Optional. Indicates that this **Sub** procedure shadows an identically named programming element, or set of overloaded elements, in a base class. You can shadow any kind of declared element with any other kind. If you shadow a procedure with another procedure, the arguments and the return type do not have to match those in the base class procedure. A shadowed element is unavailable from within the derived class that shadows it, unless the shadowing element is inaccessible, for example if it is **Private**.

You cannot specify both **Overloads** and **Shadows** in the same procedure declaration.

Shared
Optional. Indicates that this **Sub** procedure is a shared procedure. This means it is not associated with a specific instance of a class or structure. You can call a shared procedure by qualifying it either with the class or structure name, or with the variable name of a specific instance of the class or structure.

Public
Optional. Procedures declared with the **Public** keyword have public access. There are no restrictions on the accessibility of public procedures.

Protected
Optional. Procedures declared with the **Protected** keyword have protected access. They are accessible only from within their own class or from a derived class. Protected access can be specified only on members of classes. It is not a superset of friend access.

Friend
Optional. Procedures declared with the **Friend** keyword have friend access. They are accessible from within their declaration context and from anywhere else in the same program.

Protected Friend
Optional. Procedures declared with the **Protected Friend** keywords have the union of protected and friend access. They can be used by code in the same program, as well as by code in derived classes. Protected friend access can be specified only on members of classes.
Private
Optional. Procedures declared with the **Private** keyword have private access. They are accessible only from within their declaration context, including from members of any nested types such as procedures.
name
Required. Name of the **Sub** procedure. Must be a valid Visual Basic identifier.
arglist
Optional. List of variables or expressions representing arguments that are passed to the **Sub** procedure when it is called. Multiple arguments are separated by commas. If you supply an argument list, you must enclose it in parentheses.
Implements
Optional. Indicates that this **Sub** procedure implements a **Sub** procedure defined by an interface.
interface
Required if **Implements** is supplied. The interface implemented by the class or structure containing this **Sub** procedure. The class or structure must specify *interface* in an **Implements** statement immediately following the **Class** or **Structure** statement.
definedname
Required if **Implements** is supplied. The name by which the **Sub** procedure is defined in *interface*. The name of this **Sub** procedure (in *name*) does not have to be the same as *definedname*.
statements
Optional. A block of statements to be executed within the **Sub** procedure.
End Sub
Terminates the definition of this **Sub** procedure.

Each argument in the *arglist* part has the following syntax and parts:

```
[ <attrlist> ] [ Optional ] [{ ByVal | ByRef }] [ ParamArray ]
argname[( )] [ As argtype ] [ = defaultvalue ]
```

***arglist* Parts**

attrlist
Optional. List of attributes that apply to this argument. Multiple attributes are separated by commas.
Optional
Optional. Indicates that this argument is not required when the procedure is called. If this keyword is used, all subsequent arguments in *arglist* must also be optional and be declared using the **Optional** keyword. Every optional argument declaration must supply the *defaultvalue* clause. **Optional** cannot be used for any argument if **ParamArray** is used.
ByVal
Optional. Indicates that the procedure cannot replace or reassign the underlying variable element in the calling code. However, if the argument is a reference type, the procedure can modify the contents or members of the underlying object. **ByVal** is the default in Visual Basic.
ByRef
Optional. Indicates that the procedure can modify the underlying variable in the calling code the same way the calling code itself can.
ParamArray
Optional. Used only as the last argument in *arglist* to indicate that the final argument is an optional array of elements of the specified type. The **ParamArray** keyword allows you to pass an arbitrary number of arguments to the procedure. A **ParamArray** argument is always passed **ByVal**.
argname
Required. Name of the variable representing the argument. Must be a valid Visual Basic identifier.
argtype
Optional unless **Option Strict** is **On**. Data type of the argument passed to the procedure. Can be **Boolean**, **Byte**, **Char**, **Date**, **Decimal**, **Double**, **Integer**, **Long**, **Object**, **Short**, **Single**, or **String**; or the name of an enumeration, structure, class, or interface.
defaultvalue
Required for **Optional** arguments. Any constant or constant expression that evaluates to the data type of the argument. If the type is **Object**, or a class, interface, array, or structure, the default value can only be **Nothing**.

Each attribute in the *attrlist* part has the following syntax and parts:

```
attrname [({ attrargs | attrinit })]
```

attrlist Parts

attrname
Required. Name of the attribute. Must be a valid Visual Basic identifier.
attrargs
Optional. List of positional arguments for this attribute. Multiple arguments are separated by commas.
attrinit
Optional. List of field or property initializers for this attribute. Multiple initializers are separated by commas.

Remarks

All executable code must be in procedures. You can define a **Sub** procedure inside a module, class, interface, or structure, but not inside another procedure.

Sub procedures are **Public** by default. To specify a different accessibility, include **Protected**, **Friend**, **Protected Friend**, or **Private** in the declaration.

When the **Sub** procedure returns to the calling program, execution continues with the statement following the statement that called it.

The **Exit Sub** statement causes an immediate exit from a **Sub** procedure. Any number of **Exit Sub** statements can appear anywhere in the procedure.

You can also use the **Return** statement to immediately exit the procedure, as the following example shows:

```
Sub MySub(ByVal Q As String)
   ' ...
   Return
   ' ...
End Sub
```

Any number of **Return** statements can appear anywhere in the procedure. You can also mix **Exit Sub** and **Return** statements.

A **Sub** procedure, like a **Function** procedure, is a separate procedure that can take arguments and perform a series of statements. However, unlike a **Function** procedure, which returns a value, a **Sub** procedure cannot be used in an expression.

You call a **Sub** procedure by using the procedure name, followed by the argument list in parentheses, in a statement. You can omit the parentheses only if you are not supplying any arguments. You can optionally use the **Call** statement to call a **Sub** procedure. This can improve the readability of your program.

Example

This example uses the **Sub** statement to define the name, arguments, and code that form the body of a **Sub** procedure.

```
' Sub procedure definition.
' Sub procedure with two arguments.
Sub SubComputeArea(ByVal Length As Double, ByVal Width As Double)
   Dim Area As Double   ' Declare local variable.
   If Length = 0 Or Width = 0 Then
      ' If either argument = 0.
      Exit Sub ' Exit Sub immediately.
   End If
   Area = Length * Width   ' Calculate area of rectangle.
   Debug.WriteLine(Area)   ' Print Area to Immediate window.
End Sub
```

See Also

Call Statement | Function Statement | Dim Statement | Implements Statement

SyncLock Statement

Allows statements to be synchronized on a single expression.

```
SyncLock expression
...[ block ]
End SyncLock
```

Parts

expression
Required. A unique collection of operators and values that yield a single result.

block
Optional. The statements that will execute in sequence.

End SyncLock
Terminates a **SyncLock** procedure.

Remarks

The **SyncLock** statement ensures that multiple threads do not execute the same statements at the same time. When the thread reaches the **SyncLock** block, it evaluates the expression and maintains this exclusivity until it has a lock on the object that is returned by the expression. This prevents an expression from changing values during the running of several threads, which can give unexpected results from your code.

> **Note** The type of the expression in a **SyncLock** statement must be a reference type, such as a class, a module, an interface, array or delegate.

Example

```
Class Cache
   Private Shared Sub Add(ByVal x As Object)
      SyncLock GetType(Cache)
      End SyncLock
   End Sub

   Private Shared Sub Remove(ByVal x As Object)
      SyncLock GetType(Cache)
      End SyncLock
   End Sub
End Class
```

See Also

Thread Synchronization | Multithreading in Visual Basic .NET

Throw Statement

Throws an exception within a procedure.

```
Throw expression
```

Part

expression
Required. Provides information about the exception to be thrown.

Remarks

The **Throw** statement throws an exception that you can handle with structured exception-handling code (**Try**...**Catch**...**Finally**) or unstructured exception-handling code (**On Error GoTo**). You can use the **Throw** statement to trap errors within your code, because Visual Basic moves up the call stack until it finds the appropriate exception-handling code.

Example

The following code uses the **Throw** statement to throw an exception:

```
' Throws a new exception.
Throw New System.Exception("An exception has occurred.")
```

Requirements

Namespace: Microsoft.VisualBasic

Module: Interaction

Assembly: Microsoft Visual Basic .NET Runtime (in Microsoft.VisualBasic.dll)

See Also

Try...Catch...Finally Statements | On Error Statement | Structured Exception Handling | Unstructured Exception Handling

Try...Catch...Finally Statements

Provides a way to handle some or all possible errors that may occur in a given block of code, while still running code.

```
Try
   [ tryStatements ]
[ Catch [ exception [ As type ] ] [ When expression ]
   [ catchStatements ] ]
[ Exit Try ]
...
[ Finally
   [ finallyStatements ] ]
End Try
```

Parts

tryStatements
Optional. Statement(s) where an error can occur. Can be a compound statement.

Catch
Optional. Multiple **Catch** blocks permitted. If an exception occurs while processing the **Try** block, each **Catch** statement is examined in textual order to determine if it handles the exception. *Exception* represents the exception that has been thrown.

exception
Optional. Any variable name. The initial value of *exception* is the value of the thrown error. Used with **Catch** to specify the error caught.

type
Optional. Specifies the type of class filter. If the value of *exception* is of the type specified by *type* or of a derived type, the identifier becomes bound to the exception object.

When
Optional. A **Catch** statement with a **When** clause will only catch exceptions when *expression* evaluates to **True**. A **When** clause is only applied after checking the type of the exception, and *expression* may refer to the identifier representing the exception.

expression
Optional. Must be implicitly convertible to **Boolean**. Any expression that describes a generic filter. Typically used to filter by error number. Used with **When** keyword to specify circumstances under which the error is caught.

catchStatements
Optional. Statement(s) to handle errors occurring in the associated **Try** block. Can be a compound statement.

Exit Try
Optional. Keyword that breaks out of the **Try...Catch...Finally** structure. Execution resumes with the **Finally** block if present, otherwise with the code immediately following the **End Try** statement. Not allowed in **Finally** blocks.

Finally
Optional. A **Finally** block is always executed when execution leaves any part of the **Try** statement.

finallyStatements
Optional. Statement(s) that are executed after all other error processing has occurred.

End Try
Terminates the **Try...Catch...Finally** structure.

Remarks

Local variables from a **Try** block are not available in a **Catch** block because they are separate blocks. If you want to use a variable in more than one block, declare the variable outside the **Try...Catch...Finally** structure.

If errors occur that the programmer has not handled, Visual Studio for Applications simply provides its normal error message to a user, as if there was no error handling.

The **Try** block contains code where an error can occur, while the **Catch** block contains code to handle any error that does occur. If an error occurs in the **Try** block, program control is passed to the appropriate **Catch** statement for disposition. The *exception* argument is an instance of the **Exception** class or an instance of a class that derives from the **Exception** class corresponding to the error that occurred in the **Try** block. The **Exception** class instance contains information about the error including, among other things, its number and message.

In partial trust situations, such as an application hosted on a network share, **Try...Catch...Finally** will not catch security exceptions that occur before the method containing the call is invoked. The following example, when placed on a server share and run from there, for example, will produce the error: "Sub System.Security.SecurityException: Request Failed. For more information on

Security Exceptions, see SecurityException Class.

```
Private Sub Button1_Click(ByVal sender As System.Object, ByVal e As _
System.EventArgs) Handles Button1.Click
   Try
      Process.Start("http://www.microsoft.com")
   Catch ex As Exception
      MsgBox("Can't load Web page" & vbCrLf & ex.Message)
   End Try
End Sub
```

In such a partial trust situation, you would need to put the Process.Start statement in a separate **Sub**. The initial call to the **Sub** will fail, allowing **Try...Catch** to catch it before the Sub containing Process.Start is launched and the security exception produced.

Note If a **Try** statement does not contain at least one **Catch** block it must contain a **Finally** block.

Example

The following simplified example illustrates the structure of the **Try...Catch...Finally** statement:

```
Public Sub TryExample()
   Dim x As Integer = 5   ' Declare variables.
   Dim y As Integer = 0
   Try   ' Set up structured error handling.
      x /= y   ' Cause a "Divide by Zero" error.
   Catch ex As Exception When y = 0   ' Catch the error.
      MsgBox(ex.toString)   ' Show friendly error message.
   Finally
      Beep()   ' Beep after error processing.
   End Try
End Sub
```

See Also

End Statement | Err Object | Exit Statement | On Error Statement | Try...Catch...Finally Statements (Conceptual) | Exception Class

While...End While Statements

Executes a series of statements as long as a given condition is **True**.

```
While condition
   [ statements ]
End While
```

Parts

condition
Required. Expression. Must evaluate to **True** or **False**. If *condition* is **Nothing**, *condition* is treated as **False**.
statements
Optional. One or more statements following **While** that are executed while *condition* is **True**.
End While
Terminates execution of the **While** block.

Remarks

If *condition* is **True**, all of the *statements* are executed until the **End While** statement is encountered. Control then returns to the **While** statement and *condition* is again checked. If *condition* is still **True**, the process is repeated. If it is **False**, execution resumes with the statement following the **End While** statement.

You can nest **While** loops by placing one loop within another.

Example

This example uses the **While...End While** statement to increment a counter variable. The statements in the loop are executed as long as the condition evaluates to **True**.

```
Dim Counter As Integer = 0
While Counter < 20   ' Test value of Counter.
   Counter += 1   ' Increment Counter.
End While   ' End While loop when Counter > 19.
Debug.WriteLine (Counter)   ' Prints 20 in the Output window.
```

See Also

Do...Loop Statements | Do...Loop Statements (Conceptual) | With...End With Statements | While Statement (Conceptual)

With...End With Statements

Executes a series of statements making repeated reference to a single object or structure.

```
With object
   [ statements ]
End With
```

Parts

object
Required. Expression. Can evaluate to any data type, including elementary types.
statements
Optional. One or more statements following **With** that are executed on *object*.
End With
Terminates execution of the **With** block.

Remarks

With...End With allows you to perform a series of statements on a specified object without requalifying the name of the object. For example, to change a number of different properties on a single object, place the property assignment statements within the **With...End With**, referring to the object once instead of referring to it with each property assignment. The following example illustrates use of **With...End With** to assign values to several properties of the same object:

```
With MyLabel
   .Height = 2000
   .Width = 2000
   .Text = "This is MyLabel"
End With
```

> **Note** Once you have entered a **With...End With**, you cannot reassign *object* until you have passed the **End With**. Therefore, you can access the methods and properties of only the specified object without qualifying them. You can use methods and properties of other objects, but you must qualify them with their object names.

You can nest **With...End With** statements by placing one within another. However, because members of outer statements are masked inside the inner statements, you must provide a fully qualified object reference in an inner **With...End With** to any member of an object in an outer statement.

You cannot use **GoTo** to branch from outside a **With...End With** to a label inside it. If you with to exit before all the statements have been executed, put a label on the **End With** statement and branch to that.

Example

This example uses the **With** statement to execute a series of statements on a single object. The object `MyObject` and its properties are generic names used for illustration purposes only.

```
With MyObject
   .Height = 100   ' Same as MyObject.Height = 100.
   .Text = "Hello World"   ' Same as MyObject.Text = "Hello World".
   .ForeColor = Color.Green   ' Same as MyObject.ForeColor = Color.Green.
   .Font = New Font(.Font, FontStyle.Bold)   ' Same as:
                ' MyObject.Font = New Font(MyObject.Font, FontStyle.Bold).
End With
```

With...End With Statements (Conceptual)

Error Messages

Error messages can occur while an application is running, either within the Visual Basic .NET environment or as a stand-alone executable. Some of these can also occur during design time or compile time. You can test and respond to trappable errors using the **On Error** statement and the **Err** object's **Number** property. Unused error numbers in the range 1 to 1000 are reserved for future use by Visual Basic.

> **Note** The description "Application-defined or object-defined error" occurs when an error is generated using the **Err** object's **Raise** method or the **Error** statement, but the number does not correspond to an error defined by the Visual Basic language. Such errors may be defined by the host application (for example, Microsoft Excel or Visual Basic), but if you want to generate them from code, you must use the **Raise** method, and fill in all relevant arguments.

While developing in Visual Basic you can get information from Help on a message by pressing F1. Likewise, you press F1 on error messages shown in the Task List window.

In This Section

Visual Basic Compiler Errors

Related Sections

Exception Handling
Lists links to topics related to exception handling in Visual Basic .NET.
Walkthrough: Structured Exception Handling
Illustrates how to use the **Try...Catch...Finally** statement to handle exceptions.

Visual Basic Compiler Errors

Visual Basic compiler errors occur when the compiler encounters problems in the code. The code causing the errors is marked with a wavy line underneath it in the Code Editor, and when your mouse pauses over the marked code, the error message appears. The messages also appear in the Task List.

To get help for a particular error message

- Highlight the error message in the **Task List** and press F1.

-or-

1. Click **Search** on the **Help** menu.
2. Type the error message in the **Look for** box in the Search window.

> **Note** Remember that displayed error messages often incorporate identifiers from the code, such as variable or project names, as well as the type names for these elements; these are not part of the underlying error message. Be careful not to include these words as part of your search.

See Also

Visual Basic Run-Time Errors | Debugging Code in the Editor

Visual Basic Run-Time Errors

Visual Basic run-time errors occur when an application attempts to perform an action that the system cannot execute.

The errors that Visual Basic .NET throws are **Error** objects. Visual Basic .NET can generate custom errors of any data type, including **Error** objects, by using the **Throw** statement. A program can display the error number and message of a caught **Error** to identify the error. If an error is not caught, the program ends.

Run-time errors can be trapped and examined by the code. By enclosing the code that produces the error in a **Try** block, any thrown error can be caught within a matching **Catch** block.

To get help for a particular error message

1. Click **Search** on the **Help** menu.
2. Type the error message in the **Look for** box in the Search window.

> **Note** Some error messages include words in single quotes that refer to identifiers from the code, such as a project or variable name, and are not part of the error message. Do not include the quoted words as part of your search.

Visual Basic and Visual C#
Covers designing, developing, debugging, testing, and deploying applications using Visual Basic or Visual C#.

Building From the Command Line

A Visual Basic .NET project is made up of one or more separate source files. During the process known as *compilation*, these files are brought together into one package — a single executable file that can be run as an application.

Visual Basic .NET provides a command-line compiler as an alternative to compiling programs from within the Visual Studio .NET integrated development environment (IDE). The command-line compiler is designed for situations in which you do not require the full set of features in the IDE; for example, when you are using or writing for computers with limited system memory or storage space.

When compiling from the command line, you must explicitly reference the Microsoft Visual Basic Run-Time Library through the **/reference** compiler option.

To compile source files from within the Visual Studio .NET IDE, choose the **Build** command from the **Build** menu. To compile project (.vbproj) files at the command line, see Devenv Command Line Switches.

In This Section

Invoking the Command-Line Compiler
Describes how to invoke the command-line compiler at the MS-DOS prompt or from a specific subdirectory.
Sample Compilation Command Lines
Provides a list of sample command lines that you can modify for your own use.

Provides lists of compiler options, organized alphabetically or by purpose.
Conditional Compilation Overview
Describes how to compile particular sections of code.
Preparing and Managing Builds
Describes how to organize what will be included in different builds, choose project properties, and ensure that projects build in the correct order.

Invoking the Command-Line Compiler

You can invoke the command-line compiler by typing the name of its executable file at the command line, also known as the MS-DOS prompt.

When compiling from the command line, you must explicitly reference the Microsoft Visual Basic Run-Time Library through the **/reference** compiler option.

To invoke the compiler

- At the command line, type **vbc.exe /reference:Microsoft.VisualBasic.dll**, and then press ENTER.

You may need to adjust your path if you want to invoke the compiler from a specific subdirectory on your computer. For example, if you stored your executables in a directory called "SourceFiles", you would open the command prompt, type "cd SourceFiles" to change to that directory, and then type **vbc.exe**.

Visual Basic Compiler Options | Conditional Compilation Overview | /reference

Sample Compilation Command Lines

As an alternative to compiling Visual Basic .NET programs from within Visual Studio .NET, you can compile from the command line to produce executable (.exe) files or dynamic-link library (.dll) files.

The Visual Basic .NET command-line compiler supports a complete set of options that control input and output files, assemblies, and debug and preprocessor options. Each option is available in two interchangeable forms: **-***option* and */option*. This documentation shows only the */option* form.

The following table lists some sample command lines you can modify for your own use.

To	Use
Compile File.vb and create File.exe	**vbc /reference:Microsoft.VisualBasic.dll File.vb**
Compile File.vb and create File.dll	**vbc /target:library File.vb**
Compile File.vb and create My.exe	**vbc /out:My.exe File.vb**
Compile all Visual Basic files in the current directory, with optimizations on and the DEBUG symbol defined, producing File2.exe	**vbc /define:DEBUG=1 /optimize /out:File2.exe *.vb**
Compile all Visual Basic files in the current directory, producing a debug version of File2.dll without displaying the logo or warnings	**vbc /target:library /out:File2.dll /warn:0 /nologo /debug *.vb**
Compile all Visual Basic files in the current directory to Something.dll	**vbc /target:library /out:Something.dll *.vb**

When compiling from the command line, you must explicitly reference the Microsoft Visual Basic Run-Time Library through the **/reference** compiler option.

Visual Basic Compiler Options | Conditional Compilation Overview

Visual Basic Compiler Options Listed Alphabetically

The Visual Basic .NET command-line compiler is provided as an alternative to compiling programs from within the Visual Studio .NET integrated development environment (IDE). The following is a list of the Visual Basic command-line compiler options sorted alphabetically.

Option	Purpose
@ (Specify Response File)	Specifies a response file.
/?	Displays compiler options. This command is the same as specifying the **/help** option. No compilation occurs.
/addmodule	Causes the compiler to make all type information from the specified file(s) available to the project you are currently compiling.
/baseaddress	Specifies the base address of a DLL.
/bugreport	Creates a file that contains information that makes it easy to report a bug.
/debug	Produces debugging information.
/define	Defines symbols for conditional compilation.
/delaysign	Specifies whether the assembly will be fully or partially signed.
/help	Displays compiler options. This command is the same as specifying the **/?** option. No compilation occurs.
/imports	Imports a namespace from a specified assembly.
/keycontainer	Specifies a key container name for a key pair to give an assembly a strong name.
/keyfile	Specifies a file containing a key or key pair to give an assembly a strong name.
/libpath	Specifies the location of assemblies referenced via the /reference option.
/linkresource	Creates a link to a managed resource.
/main	Specifies the class that contains the **Sub Main** procedure to use at startup.
/netcf	Sets the compiler to target the .NET Compact Framework.
/nologo	Suppresses compiler banner information.
/nowarn	Suppresses the compiler's ability to generate warnings.
/optimize	Enables/disables code optimization.
/optioncompare	Determines whether string comparisons should be binary or use locale-specific text semantics.
/optionexplicit	Requires explicit declaration of variables.
/optionstrict	Enforces strict language semantics.
/out	Specifies an output file.
/quiet	Prevents the compiler from displaying code for syntax-related errors and warnings.
/recurse	Searches subdirectories for source files to compile.
/reference	Imports metadata from an assembly.
/removeintchecks	Disables integer overflow checking.
/resource	Embeds a managed resource in an assembly.
/rootnamespace	Specifies a namespace for all type declarations.
/sdkpath	Specifies the location of mscorlib.dll and microsoft.visualbasic.dll.
/target	Specifies the format of the output file using one of four options: /target:exe, /target:library, /target:module, or /target:winexe.
/utf8output	Displays compiler output using UTF-8 encoding.
/verbose	Outputs extra information during compilation.
/warnaserror	Promotes warnings to errors.
/win32icon	Inserts a .ico file into the output file.
/win32resource	Inserts a Win32 resource into the output file.

See Also

Visual Basic Compiler Options Listed by Category | <Projectname> Property Pages Dialog Box

/help, /?

Displays the compiler options.

```
/help
```

-or-

```
/?
```

Remarks

If you include this option in a compilation, no output file is created and no compilation takes place.

> **Note** The **/help** option is not available from within the Visual Studio development environment; it is available only when compiling from the command line. It cannot be changed programmatically.

Example

The following code displays help from the command line:

```
vbc /help
```

See Also

Visual Basic Compiler Options | Sample Compilation Command Lines

@ (Specify Response File)

Specifies a file that contains compiler options and source code files to compile.

```
@response_file
```

Arguments

response_file
Required. A file that lists compiler options or source code files to compile.

Remarks

The compiler processes the compiler options and source code files specified in a response file as if they had been specified on the command line.

To specify more than one response file in a compilation, specify multiple response file options. For example:

```
@file1.rsp @file2.rsp
```

In a response file, multiple compiler options and source code files can appear on one line. A single compiler option specification must appear on one line (cannot span multiple lines). Response files can have comments that begin with the # symbol.

You can combine options specified on the command line with options specified in one or more response files. The compiler processes the command options as it encounters them. Therefore, command-line arguments can override previously listed options in response files. Conversely, options in a response file override options listed previously on the command line or in other response files.

> **Note** The **@** option is not available from within the Visual Studio development environment; it is available only when compiling from the command line. It cannot be changed programmatically.

Example

The following are a few lines from a sample response file:

```
# build the first output file
/target:exe
/out:MyExe.exe
source1.vb
source2.vb
```

See Also

Visual Basic Compiler Options | Sample Compilation Command Lines

/addmodule

Causes the compiler to make all type information from the specified file(s) available to the project you are currently compiling.

```
/addmodule:module[,module2]
```

Arguments

module, *module2*
Required. A file that contains metadata but not an assembly manifest. To import more than one file, separate file names with a comma.

Remarks

module is a file created with /target:module, or another compiler's equivalent to **/target:module**.

All modules added with **/addmodule** must be in the same directory as the output file at run time. That is, you can specify a module in any directory at compile time, but the module must be in the application directory at run time. If it is not, you get a **System.TypeLoadException** error.

If you specify (implicitly or explicitly) any /target option other than **/target:module** with **/addmodule**, the files you pass to **/addmodule** become part of the project's assembly. An assembly is required to run an output file that has one or more files added with **/addmodule**.

Use /reference to import metadata from a file that contains an assembly.

> **Note** The **/addmodule** option is not available from within the Visual Studio development environment; it is available only when compiling from the command line. It cannot be changed programmatically.

Example

The following code creates a module:

```
' t1.vb
' Compile with vbc /target:module t1.vb.
' Outputs t1.netmodule.

Public class TestClass
   Public i As Integer
End class
```

The following code imports the module's types:

```
' t2.vb
' Compile with vbc /addmodule:t1.netmodule t2.vb.
Option Strict Off
Module Module1
   Sub Main()
      Dim x As TestClass
      x = New TestClass
      x.i = 802
      System.Console.WriteLine(x.i)
   End Sub
End Module
```

When you run `t1`, it outputs `802`.

See Also

Visual Basic Compiler Options | /target | Sample Compilation Command Lines

/baseaddress

Specifies a default base address when creating a DLL.

```
/baseaddress:address
```

Arguments

address
Required. The base address for the DLL. This address must be specified as a hexadecimal number.

Remarks

The default base address for a DLL is set by the .NET Framework.

Be aware that the lower-order word in this address is rounded. For example, if you specify 0x11110001, it is rounded to 0x11110000.

To complete the signing process for a DLL, use the **–R** option of the Strong Naming tool (Sn.exe).

This option is ignored if the target is not a DLL.

To set /baseaddress in the Visual Studio integrated development environment

1. Open the project's Property Pages dialog box. For details, see <Projectname> Property Pages Dialog Box.
2. Click the Configuration Properties folder.
3. Click the Optimizations property page.
4. Modify the DLL base address property.

To set /baseaddress programmatically

- See BaseAddress Property.

See Also

Visual Basic Compiler Options | /target | Sample Compilation Command Lines

/bugreport

Creates a file you can use when filing a bug report.

```
/bugreport:file
```

Arguments

file
Required. The name of the file that will contain your bug report.

Remarks

The following information is placed in *file*:

- A copy of all source code files in the compilation.
- A list of the compiler options used in the compilation.
- Version information about your compiler, common language runtime, and operating system.
- Compiler output, if any.
- A description of the problem, for which you are prompted.
- A description of how you think the problem should be fixed, for which you are prompted.

Because a copy of all source code files is placed in *file*, you may want to reproduce the (suspected) code defect in the shortest possible program.

> **Note** The **/bugreport** option is not available from within the Visual Studio development environment; it is available only when compiling from the command line. It cannot be changed programmatically.
>
> **Security Note** The **/bugreport** option produces a file that contains potentially sensitive information including: current time, compiler version, .NET Framework version, OS version, user name, the command-line arguments with which the compiler was run, all source code, and the binary form of any referenced assembly. This option can be accessed by specifying command-line options in the web.config file for a server-side compilation of an ASP.NET application. To prevent this from happening, disallow users from compiling on the server via the machine.config file.

Example

The following example compiles `t2.vb` and puts all bug reporting information in the file `problem.txt`:

```
vbc /bugreport:problem.txt t2.vb
```

See Also

Visual Basic Compiler Options | /debug | Sample Compilation Command Lines | Machine Configuration Files | <trustlevel>

/debug

Causes the compiler to generate debugging information and place it in the output file(s).

```
/debug[+ | -]
```

-or-

```
/debug:[full | pdbonly]
```

Arguments

+ | -
Optional. Specifying +, or just **/debug**, causes the compiler to generate debugging information and place it in a .pdb file. Specifying -, which is in effect if you do not specify **/debug**, causes no debug information to be created.

full | pdbonly
Optional. Specifies the type of debugging information generated by the compiler. *full*, which is in effect if you do not specify **/debug:pdbonly**, enables attaching a debugger to the running program. *pdbonly* allows source code debugging when the program is started in the debugger, but displays assembly-language code only when the running program is attached to the debugger.

Remarks

Use this option to create debug builds. If you do not specify **/debug**, **/debug+**, or **/debug:full**, you will be unable to debug the output file of your program.

By default, debugging information is not emitted (**/debug**-). To emit debugging information, specify **/debug** or **/debug+**.

For information on how to configure the debug performance of an application, see Making an Image Easier to Debug.

To set /debug in the Visual Studio integrated development environment

1. Open the project's Property Pages dialog box. For details, see <Projectname> Property Pages Dialog Box.
2. Click the Configuration Properties folder.
3. Click the Build property page.
4. Select the Generate debugging information check box.

To set /debug programmatically

- See DebugSymbols Property.

Example

The following example puts debugging information in output file `app.exe`:

```
vbc /debug /out:app.exe test.vb
```

See Also

Visual Basic Compiler Options | /bugreport | Sample Compilation Command Lines

/define

Defines conditional compiler constants.

```
/define:symbol=value[,symbol=value]
```

-or-

```
/d:symbol=value[,symbol=value]
```

Arguments

symbol
Required. The symbol to define.
value
Required. The value to assign *symbol*.

Remarks

The **/define** option has the same effect as using a **#Const** preprocessor directive in your source file.

You can use symbols created by this option with the **#If...Then...#Else** directive to compile source files conditionally.

/d is the short form of **/define**.

You can define multiple symbols with **/define** by using a comma to separate symbol definitions.

To set /define in the Visual Studio integrated development environment

1. Open the project's Property Pages dialog box. For details, see <Projectname> Property Pages Dialog Box.
2. Click the Configuration Properties folder.
3. Click the Build property page.
4. Modify the Conditional compilation constants property.

To set /define programmatically

- See DefineConstants Property.

Example

The following code defines and then uses two conditional compiler constants:

```
Vbc /define:DEBUGMODE=True,TRAPERRORS=False test.vb
Sub mysub()
   #If debugmode Then
      ' Place debug statements here.
       MsgBox("debug mode")
   #Else
      ' Place default statements here.
      '
   #End If
End Sub
```

See Also

Visual Basic Compiler Options | #If...Then...#Else Directives | #Const Directive | Sample Compilation Command Lines

/delaysign

Specifies whether the assembly will be fully or partially signed.

```
/delaysign[+ | -]
```

Arguments

+ | -
Use **/delaysign-** if you want a fully signed assembly. Use **/delaysign+** if you only want to place the public key in the assembly. The default is **/delaysign-**.

Remarks

The **/delaysign** option has no effect unless used with /keyfile or /keycontainer.

When you request a fully signed assembly, the compiler hashes the file that contains the manifest (assembly metadata) and signs that hash with the private key. The resulting digital signature is stored in the file that contains the manifest. When an assembly is delay signed, the compiler does not compute and store the signature, but reserves space in the file so the signature can be added later.

For example, using **/delaysign**+ allows a tester to put the assembly in the global cache. After testing, you can fully sign the assembly by placing the private key in the assembly.

See Creating and Using Strong-Named Assemblies for more information on signing an assembly.

This option is not available within the development environment.

To set /delaysign programmatically

- See DelaySign Property.

See Also

Visual Basic Compiler Options | /keyfile | /keycontainer | Sample Compilation Command Lines

/help, /?

Displays the compiler options.

```
/help
```

-or-

```
/?
```

Remarks

If you include this option in a compilation, no output file is created and no compilation takes place.

> **Note** The **/help** option is not available from within the Visual Studio development environment; it is available only when compiling from the command line. It cannot be changed programmatically.

Example

The following code displays help from the command line:

```
vbc /help
```

See Also

Visual Basic Compiler Options | Sample Compilation Command Lines

/imports

Imports a namespace from a specified assembly.

```
/imports:namespace[, namespace]
```

Arguments

namespace
Required. The namespace to be imported.

Remarks

The **/imports** option imports any namespace defined within the current set of source files or from any referenced assembly.

The members in a namespace specified with **/imports** are available to all source code files in the compilation. Use the Imports Statement to use a namespace in a single source code file.

To set /imports in the Visual Studio integrated development environment

1. Open the project's Property Pages dialog box. For details, see <Projectname> Property Pages Dialog Box.
2. Click the Common Properties folder.
3. Click the Imports property page.
4. Modify the Namespace property.

To set /import programmatically

- See Add Method (Imports Object).

Example

The following code compiles when **/imports:system** is specified:

```
Module MyModule
   Sub Main
      Console.WriteLine("test")
      ' Otherwise, would need
      ' System.Console.WriteLine("test")
   End Sub
End Module
```

See Also

Visual Basic Compiler Options | References and the Imports Statement | Sample Compilation Command Lines

/keycontainer

Specifies a key container name for a key pair to give an assembly a strong name.

```
/keycontainer:container
```

-or-

```
/keycontainer:"container"
```

Arguments

container
Required. Container that contains the key. Place the string in double quotation marks (" ") if it contains a space.

Remarks

The compiler creates the sharable component by inserting a public key into the assembly manifest and signing the final assembly with the private key. To generate a key file, type sn -k *file* at the command line. **sn -i** installs the key pair into a container.

If you compile with **/target:module**, the name of the key file is held in the module and incorporated into the assembly that is created when you compile an assembly with /addmodule.

You can also specify this option as a custom attribute (System.Reflection.AssemblyKeyNameAttribute) in the source code for any MSIL module.

You can also pass your encryption information to the compiler with /keyfile. Use /delaysign if you want a partially signed assembly.

See Creating and Using Strong-Named Assemblies for more information on signing an assembly.

This option is not available within the development environment.

To set /keycontainer programmatically

- See AssemblyKeyContainerName Property and the AssemblyOriginatorKeyMode Property.

Example

The following code compiles source file `input.vb` and specifies a key container:

```
vbc /keycontainer:key1 input.vb
```

See Also

Assemblies | Visual Basic Compiler Options | /keyfile | Sample Compilation Command Lines

/keyfile

Specifies a file containing a key or key pair to give an assembly a strong name.

```
/keyfile:file
```

-or-

```
/keyfile:"file"
```

Arguments

file
Required. File that contains the key. Place the string in double quotation marks (" ") if it contains a space.

Remarks

The compiler inserts the public key into the assembly manifest and then signs the final assembly with the private key. To generate a key file, type sn -k *file* at the command line.

If you compile with **/target:module**, the name of the key file is held in the module and incorporated into the assembly that is created when you compile an assembly with /addmodule.

You can also pass your encryption information to the compiler with /keycontainer. Use /delaysign if you want a partially signed assembly.

You can also specify this option as a custom attribute (System.Reflection.AssemblyKeyFileAttribute) in the source code for any MSIL module.

In case both /keyfile and /keycontainer are specified (either by command line option or by custom attribute) in the same compilation, the compiler will first try the key container. If that succeeds, then the assembly is signed with the information in the key container. If the compiler does not find the key container, it will try the file specified with /keyfile. If that succeeds, the assembly is signed with the information in the key file and the key information will be installed in the key container (similar to sn -i) so that on the next compilation, the key container will be valid.

Note that a key file might contain only the public key.

See Creating and Using Strong-Named Assemblies for more information on signing an assembly.

This option is not available within the development environment.

To set /keyfile programmatically

- See AssemblyOriginatorKeyFile Property and AssemblyOriginatorKeyMode Property.

Example

The following code compiles source file `input.vb` and specifies a key file:

```
vbc /keyfile:myfile.sn input.vb
```

See Also

Assemblies | Visual Basic Compiler Options | /target:module | /reference | Sample Compilation Command Lines

/libpath

```
/libpath:dir1[,dir2]
```

Arguments

dir1
A directory for the compiler to look in if a referenced assembly is not found in either the current working directory (the directory from which you are invoking the compiler) or the common language runtime's system directory.

dir2
Additional directories to search for assembly references. Separate additional directory names with a comma.

Remarks

The **/libpath** option specifies the location of assemblies referenced via the /reference option.

The compiler searches for assembly references that are not fully qualified in the following order:

1. Current working directory. This is the directory from which the compiler is invoked.
2. The common language runtime system directory.
3. Directories specified by **/libpath**.
4. Directories specified by the LIB environment variable.

/libpath is additive; specifying it more than once appends to any prior values.

Use **/reference** to specify an assembly reference.

To set /libpath in the Visual Studio integrated development environment

1. Open the project's Property Pages dialog box. For details, see <Projectname> Property Pages Dialog Box.
2. Click the Common Properties folder.
3. Click the Reference Path property page.
4. Modify the Folder property.

To set /libpath programmatically

- See ReferencePath Property.

Example

The following code compiles `t2.vb` to create a .exe file. The compiler looks in the working directory and in the root directory of the C drive for assembly references:

```
vbc /libpath:c:\ /reference:t2.dll t2.vb
```

See Also

Assemblies | Visual Basic Compiler Options | Sample Compilation Command Lines

/linkresource

Creates a link to a managed resource.

```
/linkresource:filename[,identifier[,public|private]]
```

-or-

```
/linkres:filename[,identifier[,public|private]]
```

Arguments

filename
Required. The resource file to link to the assembly.

identifier[,public|private]
Optional. The logical name for the resource; the name used to load the resource. The default is the name of the file. Optionally, you can specify whether the file is public or private in the assembly manifest; for example, `/linkres:filename.res,myname.res,public`. By default, *filename* is public in the assembly.

Remarks

The **/linkresource** option does not embed the resource file in the output file; use the **/resource** option to do this.

/linkresource requires one of the **/target** options other than **/target:module**.

If *filename* is a .NET Framework resource file created, for example, by the Resource File Generator (Resgen.exe) or in the development environment, it can be accessed with members in the **System.Resources** namespace (see ResourceManager Class for more information). To access all other resources at run time, use the methods that begin with **GetManifestResource** in the Assembly Class class .

filename can be any file format. For example, you may want to make a native DLL part of the assembly, so it can be installed into the Global Assembly Cache and accessed from managed code in the assembly.

The short form of **/linkresource** is **/linkres**.

> **Note** The **/linkresource** option is not available from within the Visual Studio development environment; it is available only when compiling from the command line. It cannot be changed programmatically.

Example

The following code compiles `in.vb` and links to resource file `rf.resource`:

```
vbc /linkresource:rf.resource in.vb
```

See Also

Visual Basic Compiler Options | /target | /target:module | /resource | Sample Compilation Command Lines

/main

Specifies the class or module that contains the **Sub Main** procedure.

```
/main:location
```

Arguments

location
Required. A full qualification to the **Sub Main** procedure to be called when the program starts. This may be in the form **/main:module** or **/main:namespace.module**. *location* also can be a class that inherits from **System.Windows.Forms.Form**.

Remarks

Use this option when creating an executable file or Windows executable program. If the **/main** option is omitted, the compiler searches for a valid shared **Sub Main** in all public classes and modules.

See The Visual Basic Version of Hello World! for a discussion of the various forms of the **Main** procedure.

When *location* is a class that inherits from **System.Windows.Forms.Form**, vbc.exe lets you compile code at the command line that was created in the development environment:

```
' Compile with /r:System.dll,SYSTEM.WINDOWS.FORMS.DLL /main:MyC.
Public Class MyC
   Inherits System.Windows.Forms.Form
End Class
```

To set /main in the Visual Studio integrated development environment

1. Open the project's Property Pages dialog box. For details, see <Projectname> Property Pages Dialog Box.
2. Click the Common Properties folder.
3. Click the General property page.
4. Modify the Startup object property.

To set /main programmatically

- See StartupObject Property.

Example

The following code compiles `t2.vb` and `t3.vb`, specifying that the **Sub Main** procedure will be found in the `Test2` class:

```
vbc t2.vb t3.vb /main:Test2
```

See Also

Visual Basic Compiler Options | /target:winexe | /target:exe | Sample Compilation Command Lines

/netcf

Sets the compiler to target the .NET Compact Framework.

```
/netcf
```

Remarks

/netcf causes the Visual Basic compiler to target the .NET Compact Framework rather than the full .NET Framework. Language functionality that is present only in the full .NET Framework is disabled.

/netcf is designed to be used with /sdkpath. The language features disabled by **/netcf** are the same language features not present in the files targeted with **/sdkpath**.

> **Note** **/netcf** is not available from within the Visual Studio .NET integrated development environment (IDE); it is available only when compiling from the command line. It cannot be changed programmatically. **/netcf** is set when a Visual Basic .NET device project is loaded.

/netcf disables the following features:

- The End keyword to terminate execution of a program:

```
Module Module1
Sub Main()
   End   ' not valid to terminate execution with /netcf
End Sub
End Module
```

- Late binding, in all forms, is disabled. Compile-time errors are generated when recognized late-binding scenarios are encountered. The following program will compile and run without **/netcf** but will fail at compile time with **/netcf**.

```
Class LateBoundClass
   Sub S1()
   End Sub

   Default Property P1(ByVal s As String) As Integer
      Get
      End Get
      Set(ByVal Value As Integer)
      End Set
   End Property
End Class

Module Module1
   Sub Main()
      Dim o1 As Object
      Dim o2 As Object
      Dim o3 As Object
      Dim IntArr(3) As Integer

      o1 = New LateBoundClass
      o2 = 1
      o3 = IntArr

      ' Latebound calls
      o1.S1()
      o1.P1("member") = 1

      ' Dictionary member access
```

```
        o1!member = 1

        ' Latebound overload resolution
        LateBoundSub(o2)

        ' Latebound array
        o3(1) = 1
    End Sub

    Sub LateBoundSub(ByVal n As Integer)
    End Sub

    Sub LateBoundSub(ByVal s As String)
    End Sub
End Module
```

- The Auto, Ansi, and Unicode modifiers are disabled. The syntax of the Declare statement is also modified to: **Declare Sub|Function** *name* **Lib** "*library*" [**Alias** "*alias*"] [([*arglist*])]. The following code sample shows the effect of **/netcf** on a compilation:

```
' compile with: /target:library
Module Module1
   ' valid with or without /netcf
   Declare Sub DllSub Lib "SomeLib.dll" ()

   ' invalid with /netcf
   Declare Auto Sub DllSub1 Lib "SomeLib.dll" ()
   Declare Ansi Sub DllSub2 Lib "SomeLib.dll" ()
   Declare Unicode Sub DllSub3 Lib "SomeLib.dll" ()
End Module
```

- The use of Visual Basic 6.0 keywords that were removed from Visual Basic .NET generate a different error when **/netcf** is used. This affects the error messages seen for the following keywords:
  - OPEN
  - CLOSE
  - GET
  - PUT
  - PRINT
  - WRITE
  - INPUT
  - LOCK
  - UNLOCK
  - SEEK
  - WIDTH
  - NAME
  - FREEFILE
  - EOF
  - LOC
  - LOF
  - LINE
  - GET

Example

The following code compiles `myfile.vb` with the .NET Compact Framework:

```
vbc /netcf myfile.vb
```

See Also

Visual Basic Compiler Options | Sample Compilation Command Lines

/nologo

Suppresses display of the copyright banner and informational messages during compilation.

```
/nologo
```

Remarks

If you specify **/nologo**, the compiler does not display a copyright banner. By default, **/nologo** is not in effect.

> **Note** The **/nologo** option is not available from within the Visual Studio development environment; it is available only when compiling from the command line. It cannot be changed programmatically.

Example

The following code compiles `t2.vb` and does not display a copyright banner:

```
vbc /nologo t2.vb
```

See Also

Visual Basic Compiler Options | Sample Compilation Command Lines

/nowarn

Suppresses the compiler's ability to generate warnings.

```
/nowarn
```

To set /nowarn in the Visual Studio integrated development environment

1. Open the project's Property Pages dialog box. For details, see <Projectname> Property Pages Dialog Box.
2. Click the Configuration Properties folder.
3. Click the Build property page.
4. Modify the Enable build warnings property.

To set /nowarn programmatically

- See WarningLevel Property.

Example

The following code compiles `t2.vb` and does not display warnings:

```
vbc /nowarn t2.vb
```

See Also

Visual Basic Compiler Options | Sample Compilation Command Lines

/optimize

Enables or disables compiler optimizations.

```
/optimize[ + | - ]
```

Arguments

+ | -
/optimize- disables compiler optimizations. **/optimize+** enables optimizations. By default, optimizations are disabled.

Remarks

Compiler optimizations make your output file smaller, faster, and more efficient. However, because optimizations result in code rearrangement in the output file, **/optimize+** can make debugging difficult.

All modules used by an assembly must have been built using the same /optimize settings as the assembly's /optimize setting.

You can combine the **/optimize** and **/debug** options.

To set /baseaddress in the Visual Studio integrated development environment

1. Open the project's Property Pages dialog box. For details, see <Projectname> Property Pages Dialog Box.
2. Click the Configuration Properties folder.
3. Click the Optimizations property page.
4. Modify the Enable optimizations property.

To set /optimize programmatically

- See Optimize Property.

Example

The following code compiles `t2.vb` and enables compiler optimizations:

```
vbc t2.vb /optimize
```

See Also

Visual Basic Compiler Options | /debug | Sample Compilation Command Lines

/optioncompare

Specifies how string comparisons are made.

```
/optioncompare:[binary | text]
```

Remarks

You can specify **/optioncompare** in one of two forms: /optioncompare:binary to use binary string comparisons, and /optioncompare:text to use text string comparisons.

/optioncompare:binary is the default.

See Also

Visual Basic Compiler Options | /optionexplicit | /optionstrict | Sample Compilation Command Lines

/optioncompare:binary

Causes strings to be compared based on their binary representations.

```
/optioncompare:binary
```

Remarks

In Microsoft Windows, the code page being used determines the binary sort order. A typical binary sort order is shown in the following example:

```
A < B < E < Z < a < b < e < z < À < Ê < Ø < à < ê < ø
```

To set /optioncompare:binary in the Visual Studio integrated development environment

1. Open the project's Property Pages dialog box. For details, see <Projectname> Property Pages Dialog Box.
2. Click the Common Properties folder.
3. Click the Build property page.
4. Modify the Option Compare property.

To set /optioncompare:binary programmatically

- See OptionCompare Property.

Example

The following code compiles `myfile.vb` and uses binary string comparisons:

```
vbc /optioncompare:binary myfile.vb
```

See Also

Visual Basic Compiler Options | /optioncompare:text | /optionstrict | /optionexplicit | Sample Compilation Command Lines

/optioncompare:text

Causes strings to be compared based on their text representations.

```
/optioncompare:text
```

Remarks

Text-based string comparisons are based on a case-insensitive text sort order determined by your system's locale. A typical text sort order is shown in the following example:

```
(A=a) < (À = à) < (B=b) < (E=e) < (Ê = ê) < (Z=z) < (Ø = ø)
```

To set /optioncompare:text in the Visual Studio integrated development environment

1. Open the project's Property Pages dialog box. For details, see <Projectname> Property Pages Dialog Box.
2. Click the Common Properties folder.
3. Click the Build property page.
4. Modify the Option Compare property.

To set /optioncompare:text programmatically

- See OptionCompare Property.

Example

The following code compiles `myfile.vb` and uses text-based string comparisons:

```
vbc /optioncompare:text myfile.vb
```

See Also

Visual Basic Compiler Options | /optioncompare:binary | /optionstrict | /optionexplicit | Sample Compilation Command Lines

/optionexplicit

Causes the compiler to report errors if variables are not declared prior to use.

```
/optionexplicit[+ | -]
```

Arguments

+ | -
Specify **/optionexplicit+** to require explicit declaration of variables. **/optionexplicit+**, which is the same as **/optionexplicit**, is the default. **/optionexplicit-** allows implicit declaration of variables.

To set /optionexplicit in the Visual Studio integrated development environment

1. Open the project's Property Pages dialog box. For details, see <Projectname> Property Pages Dialog Box.
2. Click the Common Properties folder.
3. Click the Build property page.
4. Modify the Option Explicit property.

To set /optionexplicit programmatically

- See OptionExplicit Property.

Example

The following code compiles when **/optionexplicit-** is used:

```
Module Module1
   Sub Main()
      i = 99
      System.Console.WriteLine(i)
   End Sub
End Module
```

See Also

Visual Basic Compiler Options | /optionstrict | Sample Compilation Command Lines | Option Explicit Statement

/optionstrict

Enforces strict type semantics to restrict implicit type conversions.

```
/optionstrict[+ | -]
```

Arguments

+ | -
/optionstrict+ restricts implicit type conversion. The default for this option is **/optionstrict-**; **/optionstrict-** is the same as **/optionstrict**. Both let you use permissive type semantics.

Remarks

When **/optionstrict+** is in effect, only widening type conversions can be done implicitly. Implicit narrowing type conversions, such as assigning a **Decimal** type object to an integer type object, are reported as errors.

To set /optionstrict in the Visual Studio integrated development environment

1. Open the project's Property Pages dialog box. For details, see <Projectname> Property Pages Dialog Box.
2. Click the Common Properties folder.
3. Click the Build property page.
4. Modify the Option Strict property.

To set /optionstrict programmatically

- See OptionStrict Property.

Example

The following code compiles `test.vb` using strict type semantics:

```
vbc /optionstrict+ test.vb
```

See Also

Visual Basic Compiler Options | /optionexplicit | Sample Compilation Command Lines | Option Strict Statement

/out

Specifies the name of the output file.

```
/out:filename
```

Arguments

filename
Required. The name of the output file the compiler creates.

Remarks

The compiler expects to find one or more source code files following the **/out** option.

Specify the full name and extension of the file to create. If you do not, the .exe file takes its name from the source code file containing the **Sub Main** procedure, and the .dll file takes its name from the first source code file.

To set /out in the Visual Studio integrated development environment

1. Open the project's Property Pages dialog box. For details, see <Projectname> Property Pages Dialog Box.
2. Click the Common Properties folder.
3. Click the General property page.
4. Modify the Assembly name property.

To set /out programmatically

- See OutputFileName Property.

Example

The following code compiles `t2.vb` and creates output file `t2.exe`:

```
vbc t2.vb /out:t3.exe
```

See Also

Visual Basic Compiler Options | /target | Sample Compilation Command Lines

/quiet

Prevents the compiler from displaying code for syntax-related errors and warnings.

```
/quiet
```

Remarks

By default, **/quiet** is not in effect. When the compiler reports a syntax-related error or warning, it also outputs the line from source code. For applications that parse compiler output, it may be more convenient for the compiler to output only the text of the diagnostic.

In the following example, `Module1` outputs an error that includes source code when compiled without **/quiet**:

```
Module Module1
   Sub Main()
      x
   End Sub
End Module
```

Output:

```
E:\test\t2.vb(3) : error BC30451: Name 'x' is not declared.

        x
        ~
```

Compiled with **/quiet**, the compiler outputs only the following:

```
E:\test\t2.vb(3) : error BC30451: Name 'x' is not declared.
```

> **Note** The **/quiet** option is not available from within the Visual Studio development environment; it is available only when compiling from the command line. It cannot be accessed programmatically.

Example

The following code compiles `t2.vb` and does not display code for syntax-related compiler diagnostics:

```
vbc /quiet t2.vb
```

See Also

Visual Basic Compiler Options | Sample Compilation Command Lines

/recurse

Compiles source code files in all child directories of either the specified directory or the project directory.

```
/recurse:[dir\]file
```

Arguments

dir
Optional. The directory in which you want the search to begin. If not specified, the search begins in the project directory.
file
The file(s) to search for. Wildcard characters are allowed.

Remarks

You can use wildcards in a file name to compile all matching files in the project directory without using **/recurse**. If no output file name is specified, the compiler bases the output file name on the first input file processed. This is generally the first file in the list of files compiled when viewed alphabetically. For this reason, it is best to specify an output file using the **/out** option.

> **Note** The **/recurse** option is not available from within the Visual Studio development environment; it is available only when compiling from the command line. It cannot be changed programmatically.

Example

The following code compiles all Visual Basic files in the current directory:

```
vbc *.vb
```

The following code compiles all Visual Basic files in the Test\ABC directory and any directories below it, and then generates Test.ABC.dll:

```
vbc /target:library /out:Test.ABC.dll /recurse:Test\ABC\*.vb
```

See Also

Visual Basic Compiler Options | /out | Sample Compilation Command Lines

/reference

Causes the compiler to make type information in the specified assemblies available to the project you are currently compiling.

```
/reference:file[,file2]
```

-or-

```
/r:file[,file2]
```

Arguments

file, *file2*
One or more assemblies. To import more than one file, separate file names with a comma.

Remarks

The file(s) you import must contain assembly metadata. Only public types are visible outside the assembly. /addmodule imports metadata from a module.

At run time, you should anticipate that only one .exe assembly can be loaded per process, even though there may be times when more than one .exe might be loaded in the same process. Therefore, it is not recommended to pass an assembly built with **/target:exe** or **/target:winexe** to **/reference** if you are compiling with **/target:winexe** or **/target:exe**.

If you reference an assembly (Assembly A) which itself references another assembly (Assembly B), you need to reference Assembly B if:

- A type you use from Assembly A inherits from a type or implements an interface from Assembly B.
- You invoke a field, property, event, or method that has a return type or parameter type from Assembly B.

Use /libpath to specify the directory in which one or more of your assembly references is located.

For the compiler to recognize a type in an assembly (not a module), it must be forced to resolve the type, which you can do, for example, by defining an instance of the type. Other ways are available to resolve type names in an assembly for the compiler. For example, if you inherit from a type in an assembly, the type name then becomes known to the compiler.

/r is the short form of **/reference**.

To set /reference in the Visual Studio integrated development environment

- See the Add Reference Dialog Box.

To set /reference programmatically

- See ReferencePath Property and Add Method (References Object).

Example

The following code compiles source file `input.vb` and reference assemblies from `metad1.dll` and `metad2.dll` to produce `out.exe`:

```
vbc /reference:metad1.dll,metad2.dll /out:out.exe input.vb
```

See Also

Visual Basic Compiler Options | /target | /target:module | Public | Sample Compilation Command Lines

/removeintchecks

Turns overflow error checking for integer operations on or off.

```
/removeintchecks[+ | -]
```

Arguments

+ | -

/removeintchecks- causes the compiler to check all integer calculations for errors such as overflow or division by zero. **/removeintchecks-** is the default for this option.

Specifying **/removeintchecks** or **/removeintchecks+** prevents error checking and can make integer calculations faster. However, without error checking and if data type capacities are overflowed, incorrect results may be stored without raising an error.

To set /removeintchecks in the Visual Studio integrated development environment

1. Open the project's Property Pages dialog box. For details, see <Projectname> Property Pages Dialog Box.
2. Click the Configuration Properties folder.
3. Click the Optimizations property page.
4. Modify the Remove integer overflow checks property.

To set /removeintchecks programmatically

- See RemoveIntegerChecks Property.

Example

The following code compiles `test.vb` and turns off integer overflow error checking:

```
vbc /removeintchecks+ test.vb
```

See Also

Visual Basic Compiler Options | Sample Compilation Command Lines

/resource

Embeds a managed resource in an assembly.

```
/resource:filename[,identifier[,public|private]]
```

-or-

```
/res:filename[,identifier[,public|private]]
```

Arguments

filename
The resource file to embed in the output file. By default, *filename* is public in the assembly.

identifier[,public|private]
Optional. The logical name for the resource; the name used to load it. The default is the name of the file. Optionally, you can specify whether the resource is public or private in the assembly manifest; for example:

```
/res:filename.res,myname.res,public.
```

Remarks

Use **/resource** to link a resource to an assembly without placing the resource file in the output file.

If *filename* is a .NET Framework resource file created, for example, by the Resource File Generator (Resgen.exe) or in the development environment, it can be accessed with members in the **System.Resources** namespace (see ResourceManager Class for more information). For all other resources, use the **GetManifestResource** methods in **System.Reflection.Assembly** class to access the resource at run time.

/res is the short form of **/resource**.

To set /resource in the Visual Studio integrated development environment

1. Add a resource file to your project.
2. Select the file to embed in Solution Explorer.
3. Select Build Action for the file in the Properties Window.
4. Set Build Action to Embedded Resource.

To set /resource programmatically

- See BuildAction Property (Visual Basic and C# ProjectItem Object).

Example

The following code compiles `in.vb` and attaches resource file `rf.resource`:

```
vbc /res:rf.resource in.vb
```

See Also

Visual Basic Compiler Options | /win32resource | /linkresource | /target | /target:module | Sample Compilation Command Lines

/rootnamespace

Specifies a namespace for all type declarations.

```
/rootnamespace:namespace
```

Arguments

namespace
The name of the namespace in which to enclose all type declarations for the current project.

Remarks

If you use the Visual Studio executable (Devenv) to compile a project created in the Visual Studio integrated development environment, **/rootnamespace** lets you specify the value of the **RootNamespace** property. See Devenv Command Line Switches for more information.

Use the common language runtime MSIL Disassembler (ildasm.exe) to view the namespace names in your output file.

To set /rootnamespace in the Visual Studio integrated development environment

1. Open the project's Property Pages dialog box. For details, see <Projectname> Property Pages Dialog Box.
2. Click the Common Properties folder.
3. Click the General property page.
4. Modify the Root Namespace property.

To set /rootnamespace programmatically

- See DefaultNamespace Property (Visual Basic and C# Project Object) and DefaultNamespace Property (Visual Basic and Visual C# ProjectItem Object).

Example

The following code compiles `in.vb` and encloses all type declarations in the namespace `mynamespace`:

```
vbc /rootnamespace:mynamespace in.vb
```

See Also

Visual Basic Compiler Options | MSIL Disassembler (Ildasm.exe) | Sample Compilation Command Lines

/sdkpath

Specifies the location of mscorlib.dll and microsoft.visualbasic.dll.

```
/sdkpath path
```

Arguments

path
The directory containing the versions of mscorlib.dll and microsoft.visualbasic.dll to use for compilation. This path is not verified until it is loaded.

Remarks

This option tells the Visual Basic compiler to load the mscorlib.dll and microsoft.visualbasic.dll files from a non-default location. **/sdkpath** was designed to be used with /netcf. The .NET Compact Framework uses different versions of these support libraries to avoid the use of types and language features not found on the devices.

> **Note** **/sdkpath** is not available from within the Visual Studio .NET integrated development environment (IDE); it is available only when compiling from the command line. It cannot be changed programmatically. **/sdkpath** is set when a Visual Basic .NET device project is loaded.

Example

The following code compiles `myfile.vb` using the versions of mscorlib.dll and microsoft.visualbasic.dll found in the default installation directory of the .NET Compact Framework on the C drive:

```
vbc /sdkpath:"c:\Program Files\Microsoft Visual Studio .NET 2003\CompactFrameworkSDK\v1.0.500
0\Windows CE " myfile.vb
```

See Also

Visual Basic Compiler Options | Sample Compilation Command Lines

/target

Specifies the format of compiler output.

```
/target:[exe | library | module | winexe]
```

Remarks

Use /target:exe to create a .exe console application. This is the default if you do not specify the **/target** option.

Use /target:library to create a dynamic-link library (DLL).

Use /target:module to create a module.

Use /target:winexe to create a Windows program.

Unless you specify **/target:module**, **/target** causes a .NET Framework assembly manifest to be placed in an output file.

Each invocation of vbc.exe produces, at most, one output file. If you specify a compiler option such as **/out** or **/target** more than once, the last one the compiler sees is put into effect. Information about all files in a compilation is placed in the manifest. All output files except those created with **/target:module** contain assembly metadata in the manifest. Use MSIL Disassembler (Ildasm.exe) to view the metadata in an output file.

Example

If you create an assembly, you can indicate that all or part of your code is CLS-compliant with the CLSCompliantAttribute Class attribute, as in the following code:

```
<Assembly: System.CLSCompliant(True)>
<System.CLSCompliant(False)> _
Public Class AClass
End Class

Module Module1
   Sub Main()
   End Sub
End Module
```

See Also

Visual Basic Compiler Options | Assemblies | Sample Compilation Command Lines

/target:exe

Causes the compiler to create an executable console application.

```
/target:exe
```

-or-

```
/t:exe
```

Remarks

The **/target:exe** option is the default when no **/target** option is specified. The executable file is created with a .exe extension.

Use /target:winexe to create a Windows program executable.

Unless otherwise specified with the **/out** option, the output file name takes the name of the input file that contains the **Sub Main** procedure.

Only one **Sub Main** procedure is required in the source code files that are compiled into a .exe file. The **/main** compiler option lets you specify which class contains the **Sub Main** procedure.

/t:exe is the short form of **/target:exe**.

To set /target:exe in the Visual Studio integrated development environment

1. Open the project's Property Pages dialog box. For details, see <Projectname> Property Pages Dialog Box.
2. Click the Common Properties folder.
3. Click the General property page.
4. Modify the Output type property.

To set /target:exe programmatically

- See OutputType Property.

Example

Both of the following two command lines compile `in.vb`, creating a console application called `in.exe`:

```
vbc /target:exe in.vb
vbc in.vb
```

See Also

/main | /target | /target:library | /target:module | /target:winexe | Visual Basic Compiler Options | /out | Sample Compilation Command Lines

/target:library

Causes the compiler to create a dynamic-link library (DLL) rather than an executable (EXE) file.

```
/target:library
```

-or-

```
/t:library
```

Remarks

The dynamic-link library file is created with a .dll extension.

Unless otherwise specified with the **/out** option, the output file name takes the name of the first input file.

When building a DLL, a **Sub Main** procedure is not required.

/t:library is the short form of **/target:library**.

To set /target:library in the Visual Studio integrated development environment

1. Open the project's Property Pages dialog box. For details, see <Projectname> Property Pages Dialog Box.
2. Click the Common Properties folder.
3. Click the General property page.
4. Modify the Output type property.

To set /target:library programmatically

- See OutputType Property.

Example

The following code compiles `in.vb`, creating `in.dll`:

```
vbc /target:library in.vb
```

See Also

/target | /target:exe | /target:module | /target:winexe | Visual Basic Compiler Options | /out | Sample Compilation Command Lines

/target:module

Causes the compiler to generate a module that can be added to an assembly.

```
/target:module
```

-or-

```
/t:module
```

Remarks

The output file is created with an extension of .netmodule.

The .NET common language runtime cannot load a file that does not have an assembly. However, you can incorporate such a file into the assembly manifest of an assembly by using **/reference**.

When code in one module references internal types in another module, both modules must be incorporated into an assembly manifest by using **/reference**.

/addmodule imports metadata from a module.

The short form of **/target:module** is **/t:module**.

> **Note** The **/target:module** option is not available from within the Visual Studio development environment; it is available only when compiling from the command line. It cannot be changed programmatically.

Example

The following code compiles `in.vb`, creating `in.netmodule`:

```
vbc /target:module in.vb
```

See Also

/reference | /target | /target:exe | /target:library | /target:winexe | Visual Basic Compiler Options | Sample Compilation Command Lines

/target:winexe

Causes the compiler to create an executable Windows program.

```
/target:winexe
```

-or-

```
/t:winexe
```

Remarks

The executable file is created with a .exe extension. A Windows program is one that provides a user interface from either the Services Framework class library or with the Win32 APIs.

Use /target:exe to create a console application.

Unless otherwise specified with the **/out** option, the output file name takes the name of the input file that contains the **Sub Main** procedure.

Only one **Sub Main** procedure is required in the source code files that are compiled into a .exe file. The **/main** compiler option lets you specify which class contains the **Sub Main** procedure in cases where your code has more than one class with a **Sub Main** procedure.

The short form of **/target:winexe** is **/t:winexe**.

To set /target:winexe in the Visual Studio integrated development environment

1. Open the project's Property Pages dialog box. For details, see <Projectname> Property Pages Dialog Box.
2. Click the Common Properties folder.
3. Click the General property page.
4. Modify the Output type property.

To set /target:winexe programmatically

- See OutputType Property.

Example

The following code compiles `in.vb` into a Windows program:

```
vbc /target:winexe in.vb
```

See Also

/main | /target | /target:exe | /target:library | /target:module | /out | Visual Basic Compiler Options | Sample Compilation Command Lines

/utf8output

Displays compiler output using UTF-8 encoding.

```
/utf8output[+ | -]
```

Arguments

+ | -
The default for this option is **/utf8output-**, which means compiler output does not use UTF-8 encoding. Specifying **/utf8output** is the same as specifying **/utf8output+**.

Remarks

In some international configurations, compiler output cannot be displayed correctly in the console. In such situations, use **/utf8output** and redirect compiler output to a file.

> **Note** The **/utf8output** option is not available from within the Visual Studio development environment; it is available only when compiling from the command line. It cannot be changed programmatically.

Example

The following code compiles `in.vb` and directs the compiler to display output using UTF-8 encoding:

```
vbc /utf8output in.vb
```

See Also

Visual Basic Compiler Options | Sample Compilation Command Lines

/verbose

Causes the compiler to produce verbose status and error messages.

```
/verbose[+ | -]
```

Arguments

+ | -
Specifying **/verbose** is the same as specifying **/verbose+**, which causes the compiler to emit verbose messages. The default for this option is **/verbose-**.

Remarks

/verbose displays information about the total number of errors issued by the compiler, reports which assemblies are being loaded by a module, and displays which files are currently being compiled.

> **Note** The **/verbose** option is not available from within the Visual Studio development environment; it is available only when compiling from the command line. It cannot be changed programmatically.

Example

The following code compiles `in.vb` and directs the compiler to display verbose status information:

```
vbc /verbose in.vb
```

See Also

Visual Basic Compiler Options | Sample Compilation Command Lines

/warnaserror

Causes the compiler to treat the first occurrence of a warning as an error.

```
/warnaserror[+ | -]
```

Arguments

+ | -
By default, **/warnaserror-** is in effect; warnings do not prevent the compiler from producing an output file. **/warnaserror**, which is the same as **/warnaserror+**, causes warnings to be treated as errors.

Remarks

Subsequent occurrences of the same warning are reported as warnings. The compiler produces no output file.

To set /warnaserror in the Visual Studio integrated development environment

1. Open the project's Property Pages dialog box. For details, see <Projectname> Property Pages Dialog Box.
2. Click the Configuration Properties folder.
3. Click the Build property page.
4. Modify the Treat compiler warnings as errors property.

To set /warnaserror programmatically

- See TreatWarningsAsErrors Property.

Example

The following code compiles `in.vb` and directs the compiler to display an error for the first occurrence of every warning it finds:

```
vbc /warnaserror in.vb
```

See Also

Visual Basic Compiler Options | Sample Compilation Command Lines

/win32icon

Inserts an .ico file in the output file. This .ico file represents the output file in the Windows Explorer.

```
/win32icon:filename
```

Arguments

filename
The .ico file to add to your output file.

Remarks

You can create an .ico file with the Microsoft® Windows® Resource Compiler (RC). The Resource Compiler is invoked when you compile a Visual C++ program; an .ico file is created from the .rc file. The **/win32icon** and **/win32resource** options are mutually exclusive.

See /linkresource to reference a .NET Framework resource file, or /resource to attach a .NET Framework resource file. See /win32resource to import a .res file.

To set /win32icon in the Visual Studio integrated development environment

1. Open the project's Property Pages dialog box. For details, see <Projectname> Property Pages Dialog Box.
2. Click the Common Properties folder.
3. Click the Build property page.
4. Modify the Application icon property.

To set /win32icon programmatically

- See ApplicationIcon Property.

Example

The following code compiles `in.vb` and attaches an .ico file, `rf.ico`:

```
vbc /win32icon:rf.ico in.vb
```

See Also

Visual Basic Compiler Options | Sample Compilation Command Lines

/win32resource

Inserts a Win32 resource file in the output file.

```
/win32resource:filename
```

Arguments

filename
The resource file to add to your output file.

Remarks

You can create a Win32 resource file with the Microsoft Windows Resource Compiler (RC).

A Win32 resource can contain version or bitmap (icon) information that helps identify your application in the Windows Explorer. If you do not specify **/win32resource**, the compiler generates version information based on the assembly version. The **/win32resource** and **/win32icon** options are mutually exclusive.

See /linkresource to reference a .NET Framework resource file, or /resource to attach a .NET Framework resource file.

> **Note** The **/nologo** option is not available from within the Visual Studio development environment; it is available only when compiling from the command line. It cannot be changed programmatically.

Example

The following code compiles `in.vb` and attaches a Win32 resource file, `rf.res`:

```
vbc /win32resource:rf.res in.vb
```

Visual Basic Compiler Options | Sample Compilation Command Lines

Visual Basic Compiler Options Listed by Category

The Visual Basic .NET command-line compiler is provided as an alternative to compiling programs from within the Visual Studio .NET integrated development environment (IDE). The following is a list of the Visual Basic command-line compiler options sorted by functional category.

Compiler Output

Option	Purpose
/nologo	Suppresses compiler banner information.
/utf8output	Displays compiler output using UTF-8 encoding.
/verbose	Outputs extra information during compilation.

Optimization

Option	Purpose
/optimize	Enables/disables optimizations.

Output Files

Option	Purpose
/netcf	Sets the compiler to target the .NET Compact Framework.
/out	Specifies an output file.
/target	Specifies the format of the output file using one of four options: /target:exe, /target:library, /target:module, or /target:winexe.

.NET Assemblies

Option	Purpose
/addmodule	Causes the compiler to make all type information from the specified file(s) available to the project you are currently compiling.
/delaysign	Specifies whether the assembly will be fully or partially signed.
/imports	Imports a namespace from a specified assembly.
/keycontainer	Specifies a key container name for a key pair to give an assembly a strong name.
/keyfile	Specifies a file containing a key or key pair to give an assembly a strong name.
/libpath	Specifies the location of assemblies referenced via the /reference option.
/reference	Imports metadata from an assembly.

Debugging/Error Checking

Option	Purpose
/bugreport	Creates a file that contains information that makes it easy to report a bug.
/debug	Produces debugging information.
/nowarn	Suppresses the compiler's ability to generate warnings.
/quiet	Prevents the compiler from displaying code for syntax-related errors and warnings.
/removeintchecks	Disables integer overflow checking.
/warnaserror	Promotes warnings to errors.

Help

Option	Purpose
/?	Displays the compiler options. This command is the same as specifying the **/help** option. No compilation occurs.
/help	Displays the compiler options. This command is the same as specifying the **/?** option. No compilation occurs.

Language

Option	Purpose

/optionexplicit	Requires explicit declaration of variables.
/optionstrict	Enforces strict type semantics.
/optioncompare	Determines whether string comparisons should be binary or use locale-specific text semantics.

Preprocessor

Option	Purpose
/define	Defines symbols for conditional compilation.

Resources

Option	Purpose
/linkresource	Creates a link to a managed resource.
/resource	Embeds a managed resource in an assembly.
/win32icon	Inserts an .ico file into the output file.
/win32resource	Inserts a Win32 resource into the output file.

Miscellaneous

Option	Purpose
@ (Specify Response File)	Specifies a response file.
/baseaddress	Specifies the base address of a DLL.
/main	Specifies the class that contains the **Sub Main** procedure to use at startup.
/recurse	Searches subdirectories for source files to compile.
/rootnamespace	Specifies a namespace for all type declarations.
/sdkpath	Specifies the location of mscorlib.dll and microsoft.visualbasic.dll.

Visual Basic .NET Language Specification

This document describes the Visual Basic .NET language. It is designed to be a complete language description, not a conceptual overview or a user's reference manual. For a conceptual overview, see *Visual Basic Language Features*. For language reference information, see *Visual Basic Language Reference*.

In This Section

1. Introduction
   Describes the evolution of Visual Basic and its role within .NET.
2. Lexical Grammar
   Discusses the syntax of characters, lines, identifiers, keywords, literals, and separators.
3. Preprocessing Directives
   Summarizes the role of conditional compilation, external source directives, and region directives.
4. General Concepts
   Provides an overview of the core concepts of object-oriented programming in Visual Basic: declaration spaces, inheritance, implementation, polymorphism, accessibility, scope, namespace and type names, and attributes.
5. Attributes
   Summarizes the syntax of attributes, which modify entities when being declared.
6. Source Files and Namespaces
   Explains compilation options, the **Imports** statement, and namespaces.
7. Types
   Provides an overview of Visual Basic .NET as a type-safe system: the taxonomy of value and reference types.
8. Conversions
   Discusses the grammar of changing value types: implicit and explicit conversions, widening and narrowing conversions, value and reference conversions, and cast expressions.
9. Type Members
   Discusses methods, constructors, events, constants, variables, and properties.
10. Statements
   Summarizes the syntax of executable code in Visual Basic .NET.
11. Expressions
   Summarizes the syntax of computational processes in Visual Basic .NET.
12. Visual Basic .NET Grammar Summary
   Provides an overview of the entire Visual Basic .NET grammar.

Visual Basic Language and Run-Time Reference

Visual Basic Language Features

1. Introduction

The Microsoft® Visual Basic® .NET programming language is a high-level programming language for the Microsoft .NET Framework. Although it is designed to be an approachable and easy-to-learn language, it is also powerful enough to satisfy the needs of experienced programmers. The Visual Basic .NET programming language is closely related to the Visual Basic programming language but the two languages are not the same. A discussion of the differences between Visual Basic .NET and Visual Basic 6.0 is beyond the scope of this document.

The Visual Basic .NET programming language has a syntax that is similar to English, which promotes the clarity and readability of Visual Basic .NET code. Wherever possible, meaningful words or phrases are used instead of abbreviations, acronyms, or special characters. Extraneous or unneeded syntax is generally allowed but not required.

The Visual Basic .NET programming language can be either a strongly typed or a loosely typed language. Loose typing defers much of the burden of type checking until a program is already running. This includes not only type checking of conversions but also of method calls, meaning that the binding of a method call can be deferred until run-time. This is useful when building prototypes or other programs in which speed of development is more important than execution speed. The Visual Basic .NET programming language also provides strongly typed semantics that performs all type checking at compile-time and disallows run-time binding of method calls. This guarantees maximum performance and helps ensure that type conversions are correct. This is useful when building production applications in which speed of execution and execution correctness is important.

This document describes the Visual Basic .NET language. It is meant to be a complete language description rather than a language tutorial or a user's reference manual.

1.1 Grammar Notation

1.1 Grammar Notation

This specification describes two grammars: a lexical grammar and a syntactic grammar. The lexical grammar defines how characters can be combined to form tokens; the syntactic grammar defines how the tokens can be combined to form Visual Basic .NET programs. There are also several secondary grammars used for preprocessing operations like conditional compilation.

> **Note** The grammars in this specification are designed to be human readable, not formal (that is, usable by LEX or YACC).

All of the grammars use a modified BNF notation, which **consists** of a set of productions made up of terminal and non-terminal names. A terminal name represents one or more Unicode characters. Each nonterminal name is defined by one or more productions. In a production, nonterminal names are shown in *italic type*, and terminal names are shown in a **bold type**. Text in normal type and surrounded by angle-bracket metasymbols are informal terminals (for example, "< all Unicode characters >"). Each grammar starts with the nonterminal *Start*.

Case is unimportant in Visual Basic .NET programs. For simplicity, all terminals will be given in standard casing, but any casing will match them. Terminals that are printable elements of the ASCII character set are represented by their corresponding ASCII characters. Visual Basic .NET is also width insensitive when matching terminals, allowing full-width Unicode characters to match their half-width Unicode equivalents.

A set of productions begins with the name of a nonterminal, followed by two colons and an equal sign. The right side contains a terminal or nonterminal production. A nonterminal may have multiple productions that are separated by the vertical-bar metasymbol (|). Items included in square-bracket metasymbols ([]) are optional. A plus metasymbol (+) following an item means the item may occur one or more times.

Line breaks and indentation may be added for readability and are not part of the production.

See Also

1. Introduction

2. Lexical Grammar

Compilation of a Visual Basic .NET program first involves translating the raw stream of Unicode characters into an ordered set of lexical tokens. Because the Visual Basic .NET language is not free-format, the set of tokens is then further divided into a series of logical lines. A *logical line* spans from either the start of the stream or a line terminator through to the next line terminator that is not preceded by a line continuation or through to the end of the stream.

```
Start ::= [ LogicalLine+ ]
LogicalLine ::= [ LogicalLineElement+ ] [ Comment ] LineTerminator
LogicalLineElement ::= WhiteSpace | LineContinuation | Token
Token ::= Identifier | Keyword | Literal | Separator | Operator
```

See Also

2.1 Characters and Lines | 2.2 Identifiers | 2.3 Keywords | 2.4 Literals | 2.5 Separators | 2.6 Operator Characters

2.1 Characters and Lines

Visual Basic .NET programs are composed of characters from the Unicode character set.

```
Character ::= < any Unicode character except a LineTerminator >
```

See Also

2.2 Identifiers | 2.3 Keywords | 2.4 Literals | 2.5 Separators | 2.6 Operator Characters | 2. Lexical Grammar

2.1.1 Line Terminators

Unicode line break characters separate logical lines.

```
LineTerminator ::=
   < Unicode carriage return character (0x000D) > |
   < Unicode linefeed character (0x000A) > |
   < Unicode carriage return character > < Unicode linefeed character > |
   < Unicode line separator character (0x2028) > |
   < Unicode paragraph separator character (0x2029) >
```

See Also

2.1.2 Line Continuation | 2.1.3 White Space | 2.1.4 Comments | 2.1 Characters and Lines

2.1.2 Line Continuation

A *line continuation* consists of at least one white-space character that immediately precedes a single underscore character as the last character (other than white space) in a text line. A line continuation allows a logical line to span more than one physical line. Line continuations are treated as if they were white space, even though they are not.

The following program shows some line continuations:

```
Imports System

Module Test
    Function Func( _
        ByVal Param1 As Integer, _
        ByVal Param2 As Integer )

        If (Param1 < Param2) Or _
            (Param1 > Param2) Then
            Console.WriteLine("Not equal")
        End If
    End Function
End Module
```

```
LineContinuation ::= WhiteSpace _ [ WhiteSpace+ ] LineTerminator
```

See Also

2.1.1 Line Terminators | 2.1.3 White Space | 2.1.4 Comments | 2.1 Characters and Lines |
Breaking and Combining Statements in Code (Visual Basic Language Concepts)

2.1.3 White Space

White space serves only to separate tokens and is otherwise ignored. Logical lines containing only white space are ignored.

> **Note** Line terminators are not considered white space.

```
WhiteSpace ::=
   < Unicode blank characters (class Zs) > |
   < Unicode tab character (0x0009) >
```

See Also

2.1.1 Line Terminators | 2.1.2 Line Continuation | 2.1.4 Comments | 2.1 Characters and Lines

2.1.4 Comments

A *comment* begins with a single-quote character or the keyword **REM**. A single-quote character is either an ASCII single-quote character, a Unicode left single-quote character, or a Unicode right single-quote character. Comments can begin anywhere on a source line, and the end of the physical line ends the comment. The compiler ignores the characters between the beginning of the comment and the line terminator. Consequently, comments cannot extend across multiple lines by using line continuations.

```
Comment ::= CommentMarker [ Character+ ]
CommentMarker ::= SingleQuoteCharacter | REM
SingleQuoteCharacter ::=
   ' |
   < Unicode left single-quote character (0x2018) |
   < Unicode right single-quote character (0x2019)
```

See Also

2.1.1 Line Terminators | 2.1.2 Line Continuation | 2.1.3 White Space | 2.1 Characters and Lines |
REM Statement (Visual Basic Language Reference)

2.2 Identifiers

An *identifier* is a name. Visual Basic .NET identifiers conform to the Unicode Standard Annex 15 with one exception: identifiers may begin with an underscore (connector) character. If an identifier begins with an underscore, it must contain at least one other valid identifier character to disambiguate it from a line continuation.

Regular identifiers may not match keywords, but escaped identifiers can. An *escaped identifier* is an identifier delimited by square brackets. Escaped identifiers follow the same rules as regular identifiers except that they may match keywords and may not have type characters.

This example defines a class named `class` with a shared method named `shared` that takes a parameter named `boolean` and then calls the method.

```
Imports System

Class [class]
    Shared Sub [shared](ByVal [boolean] As Boolean)
        If [boolean] Then
            Console.WriteLine("true")
        Else
            Console.WriteLine("false")
        End If
    End Sub
End Class

Module [module]
    Sub Main()
        [class].[shared](True)
    End Sub
End Module
```

Identifiers are case insensitive, so two identifiers are considered to be the same identifier if they differ only in case.

> **Note** The Unicode Standard one-to-one case mappings are used when comparing identifiers, and any locale-specific case mappings are ignored.

```
Identifier ::=
   NonEscapedIdentifier [ TypeCharacter ] |
   EscapedIdentifier
NonEscapedIdentifier ::= < IdentifierName but not Keyword >
EscapedIdentifier ::= [ IdentifierName ]
IdentifierName ::= IdentifierStart [ IdentifierCharacter+ ]
IdentifierStart ::=
   AlphaCharacter |
   UnderscoreCharacter IdentifierCharacter
IdentifierCharacter ::=
   UnderscoreCharacter |
   AlphaCharacter |
   NumericCharacter |
   CombiningCharacter |
   FormattingCharacter
AlphaCharacter ::=
   < Unicode alphabetic character (classes Lu, Ll, Lt, Lm, Lo, Nl) >
NumericCharacter ::= < Unicode decimal digit character (class Nd) >
CombiningCharacter ::= < Unicode combining character (classes Mn, Mc) >
FormattingCharacter ::= < Unicode formatting character (class Cf) >
UnderscoreCharacter ::= < Unicode connection character (class Pc) >
IdentifierOrKeyword ::= Identifier | Keyword
```

See Also

2.1 Characters and Lines | 2.3 Keywords | 2.4 Literals | 2.5 Separators | 2.6 Operator Characters | 2. Lexical Grammar | Declared Element Names (Visual Basic Language Concepts)

2.2.1 Type Characters

A *type character* denotes the type of the preceding identifier. The type character is not considered part of the identifier. If a declaration includes a type character, the type character must agree with the type specified in the declaration itself; otherwise, a compile-time error occurs. If the declaration omits the type (for example, if it does not specify an **As** clause), the type character is implicitly substituted as the type of the declaration.

No white space may come between an identifier and its type character. There are no type characters for **Byte** or **Short**, due to a lack of suitable characters.

Appending a type character to an identifier that conceptually does not have a type (for example, a namespace name) or to an identifier whose type disagrees with the type of the type character causes a compile-time error.

The following example shows the use of type characters:

```
' The follow line will cause an error: standard modules have no type.
Module Test1#
End Module

Module Test2
    ' This function takes a Long parameter and returns a String.
    Function Func$(ByVal Param&)
        ' The following line causes an error because the type character
        ' conflicts with the declared type of StringFunc and LongParam.
        Func# = CStr(Param@)

        ' The following line is valid.
        Func$ = CStr(Param&)
    End Function
End Module
```

The type character **!** presents a special problem in that it can be used both as a type character and as a separator in the language. To remove ambiguity, a **!** character is a type character as long as the character that follows it cannot start an identifier. If it can, then the **!** character is a separator, not a type character.

```
TypeCharacter ::=
   IntegerTypeCharacter |
   LongTypeCharacter |
   DecimalTypeCharacter |
   SingleTypeCharacter |
   DoubleTypeCharacter |
   StringTypeCharacter
IntegerTypeCharacter ::= %
LongTypeCharacter ::= &
DecimalTypeCharacter ::= @
SingleTypeCharacter ::= !
DoubleTypeCharacter ::= #
StringTypeCharacter ::= $
```

2.3 Keywords

A *keyword* is a word that has special meaning in a language construct. All keywords are reserved by the language and may not be used as identifiers unless the identifiers are escaped.

> **Note** **EndIf**, **GoSub**, **Let**, **Variant**, and **Wend** are retained as keywords, although they are no longer used in Visual Basic .NET.

```
Keyword ::= < member of keyword table >
```

See Also

2.1 Characters and Lines | 2.2 Identifiers | 2.4 Literals | 2.5 Separators | 2.6 Operator Characters | 2. Lexical Grammar | Visual Basic Language Keywords (Visual Basic Language Reference)

2.4 Literals

A *literal* is a textual representation of a particular value of a type. Literal types include Boolean, integer, floating point, string, character, and date.

```
Literal ::=
   BooleanLiteral |
   IntegerLiteral |
   FloatingPointLiteral |
   StringLiteral |
   CharacterLiteral |
   DateLiteral |
   Nothing
```

See Also

2.4.1 Boolean Literals | 2.4.2 Integer Literals | 2.4.3 Floating-Point Literals | 2.4.4 String Literals | 2.4.5 Character Literals | 2.4.6 Date Literals | 2.1 Characters and Lines | 2.2 Identifiers | 2.3 Keywords | 2.5 Separators | 2.6 Operator Characters | 2. Lexical Grammar

2.4.1 Boolean Literals

True and **False** are literals of the **Boolean** type that map to the true and false state, respectively.

```
BooleanLiteral ::= True | False
```

See Also

2.4.2 Integer Literals | 2.4.3 Floating-Point Literals | 2.4.4 String Literals | 2.4.5 Character Literals | 2.4.6 Date Literals | 2.4.7 Nothing | 2.4 Literals | Boolean Data Type (Visual Basic Language Reference) | Boolean Type (Visual Basic Language Concepts)

2.4.2 Integer Literals

Integer literals can be decimal (base 10), hexadecimal (base 16), or octal (base 8). A decimal integer literal is a string of decimal digits (0-9). A hexadecimal literal is **&H** followed by a string of hexadecimal digits (0-9, A-F). An octal literal is **&O** followed by a string of octal digits (0-7). Decimal literals directly represent the decimal value of the integral literal, whereas octal and hexadecimal literals represent the binary value of the integer literal (thus, `&H8000S` is –32768, not an overflow error).

The type of a literal is determined by its value or by the following type character. If no type character is specified, values in the range of the **Integer** type are typed as **Integer**; values outside the range for **Integer** are typed as **Long**. If an integer literal's type is of insufficient size to hold the integer literal, a compile-time error results.

```
IntegerLiteral ::= IntegralLiteralValue [ IntegralTypeCharacter ]
IntegralLiteralValue ::= IntLiteral | HexLiteral | OctalLiteral
IntegralTypeCharacter ::=
   ShortCharacter |
   IntegerCharacter |
   LongCharacter |
   IntegerTypeCharacter |
   LongTypeCharacter
ShortCharacter ::= S
IntegerCharacter ::= I
LongCharacter ::= L
IntLiteral ::= Digit+
HexLiteral ::= & H HexDigit+
OctalLiteral ::= & O OctalDigit+
Digit ::= 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9
HexDigit ::=
   0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | A | B | C | D | E | F
OctalDigit ::= 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7
```

See Also

2.4.1 Boolean Literals | 2.4.3 Floating-Point Literals | 2.4.4 String Literals | 2.4.5 Character Literals | 2.4.6 Date Literals | 2.4.7 Nothing | 2.4 Literals | Integer Data Type (Visual Basic Language Reference)

2.4.3 Floating-Point Literals

A floating-point literal is an integer literal followed by an optional decimal point (the ASCII period character) and mantissa, and an optional base 10 exponent. By default, a floating-point literal is of type **Double**. If the **Single**, **Double**, or **Decimal** type character is specified, the literal is of that type. If a floating-point literal's type is of insufficient size to hold the floating-point literal, a compile-time error results.

```
FloatingPointLiteral ::=
   FloatingPointLiteralValue [ FloatingPointTypeCharacter ] |
   IntLiteral FloatingPointTypeCharacter
FloatingPointTypeCharacter ::=
   SingleCharacter |
   DoubleCharacter |
   DecimalCharacter |
   SingleTypeCharacter |
   DoubleTypeCharacter |
   DecimalTypeCharacter
SingleCharacter ::= F
DoubleCharacter ::= R
DecimalCharacter ::= D
FloatingPointLiteralValue ::=
   IntLiteral . IntLiteral [ Exponent ] |
   . IntLiteral [ Exponent ] |
   IntLiteral Exponent
Exponent ::= E [ Sign ] IntLiteral

2.4.4 String Literals

A string literal is a sequence of zero or more Unicode characters beginning and ending with an ASCII double-quote character, a Unicode left double-quote character, or a Unicode right double-quote character. Within a string, a sequence of two double-quote characters is an escape sequence representing a double quote in the string. A string constant is of the **String** type.

```
Imports System

Module Test
    Sub Main()
        ' This prints out: ".
        Console.WriteLine("""")

        ' This prints out: a"b.
        Console.WriteLine("a""b")

        ' This causes a compile error due to mismatched double-quotes.
        Console.WriteLine("a"b")
    End Sub
End Module
```

Each string literal does not necessarily result in a new string instance. When two or more string literals that are equivalent according to the string equality operator using binary comparison semantics appear in the same program, these string literals refer to the same string instance. For instance, the output of the following program is **True** because the two literals refer to the same string instance.

```
Imports System

Module Test
    Sub Main()
        Dim a As Object = "hello"
        Dim b As Object = "hello"
        Console.WriteLine(a Is b)
    End Sub
End Module
```

```
StringLiteral ::=
   DoubleQuoteCharacter [ StringCharacter+ ] DoubleQuoteCharacter
DoubleQuoteCharacter ::=
   " |
   < Unicode left double-quote character (0x201C) > |
   < Unicode right double-quote character (0x201D) >
StringCharacter ::=
   < Character except for DoubleQuoteCharacter > |
   DoubleQuoteCharacter DoubleQuoteCharacter
```

2.4.5 Character Literals

A character literal represents a single Unicode character of the **Char** type. Two double-quote characters is an escape sequence representing the double-quote character.

```
Imports System

Module Test
    Sub Main()
        ' This prints out: a.
        Console.WriteLine("a"c)

        ' This prints out: ".
        Console.WriteLine(""""c)
    End Sub
End Module
```

```
CharacterLiteral ::=
   DoubleQuoteCharacter StringCharacter DoubleQuoteCharacter C
```

2.4.6 Date Literals

A date literal represents a particular moment in time expressed as a value of the **Date** type. The literal may specify both a date and a time, just a date, or just a time. If the date value is omitted, then January 1 of the year 1 in the Gregorian calendar is assumed. If the time value is omitted, then 12:00:00 AM is assumed.

To avoid problems with interpreting the year value in a date value, the year value cannot be two digits. When expressing a date in the first century AD/CE, leading zeros must be specified.

A time value may be specified either using a 24-hour value or a 12-hour value; time values that omit an **AM** or **PM** are assumed to be 24-hour values. If a time value omits the minutes, the literal **0** is used by default. If a time value omits the seconds, the literal **0** is used by default. If both minutes and second are omitted, then **AM** or **PM** must be specified. If the date value specified is outside the range of the **Date** type, a compile-time error occurs.

The following example contains several date literals.

```
Dim d As Date
d = # 8/23/1970 3:45:39AM #
d = # 8/23/1970 #              ' Date value: 8/23/1970 12:00:00AM.
d = # 3:45:39AM #              ' Date value: 1/1/1 3:45:39AM.
d = # 3:45:39 #                ' Date value: 1/1/1 3:45:39AM.
d = # 13:45:39 #               ' Date value: 1/1/1 1:45:39PM.
d = # 1AM #                    ' Date value: 1/1/1 1:00:00AM.
d = # 13:45:39PM #             ' This date value is not valid.
```

```
DateLiteral ::= # [ Whitespace+ ] DateOrTime [ Whitespace+ ] #
DateOrTime ::=
   DateValue Whitespace+ TimeValue |
   DateValue |
   TimeValue
DateValue ::=
   MonthValue / DayValue / YearValue |
   MonthValue – DayValue - YearValue
TimeValue ::=
   HourValue : MinuteValue [ : SecondValue ] [ WhiteSpace+ ] [ AMPM ]
MonthValue ::= IntLiteral
DayValue ::= IntLiteral
YearValue ::= IntLiteral
HourValue ::= IntLiteral
MinuteValue ::= IntLiteral
SecondValue ::= IntLiteral
AMPM ::= AM | PM
```

3. Preprocessing Directives

Once a file has been lexically analyzed, several kinds of source preprocessing occur. The most important, conditional compilation, determines which source is processed by the syntactic grammar; two other types of directives — external source directives and region directives — provide meta-information about the source but have no effect on compilation.

See Also

3.1 Conditional Compilation | 3.2 External Source Directives | 3.3 Region Directives | Directives (Visual Basic Language Reference)

3.1 Conditional Compilation

Conditional compilation controls whether sequences of logical lines are translated into actual code. At the beginning of conditional compilation, all logical lines are enabled; however, enclosing lines in conditional compilation statements may selectively disable those lines within the file, causing them to be ignored during the rest of the compilation process. Because the conditional compilation process is done after lexical analysis, even disabled lines must be lexically valid.

For example, the program

```
#Const A = True
#Const B = False
Class C
#If A Then
    Sub F()
    End Sub
#Else
    Sub G()
    End Sub
#End If
#If B Then
    Sub H()
    End Sub
#Else
    Sub I()
    End Sub
#End If
End Class
```

produces the exact same sequence of tokens as the program

```
Class C
    Sub F()
    End Sub

    Sub I()
    End Sub
End Class
```

```
Start ::= [ ConditionalElement+ ]
ConditionalElement ::=
   ConditionalConstantDeclaration |
   ConditionalIfGroup |
   LogicalLine
```

3.1.1 Conditional Constant Directives | 3.2 External Source Directives | 3.3 Region Directives |
Compiler Directive Summary (Visual Basic Language Reference) |
Conditional Compilation Overview (Visual Basic Language Concepts)

3.1.1 Conditional Constant Directives

Conditional constant statements define constants that exist in a separate conditional compilation declaration space scoped to the source file. The declaration space is special in that no explicit declaration of conditional compilation constants is necessary – conditional constants can be implicitly defined in a conditional compilation directive.

Prior to being assigned a value, a conditional compilation constant has the value **Nothing**. When a conditional compilation constant is assigned a value, which must be a constant expression, the type of the constant becomes the type of the value being assigned to it. A conditional compilation constant may be redefined multiple times throughout a source file.

For example, the following code prints only the string `about to print value` and the value of `Test`.

```
Imports System

Module M1
    Sub PrintValue(ByVal Test As Integer)
#Const DebugCode = True
#If DebugCode Then
        Console.WriteLine("about to print value")
#End If
#Const DebugCode = False
        Console.WriteLine(Test)
#If DebugCode Then
        Console.WriteLine("printed value")
#End If
    End Sub
End Module
```

The compilation environment may also define conditional constants in a conditional compilation declaration space.

```
ConditionalConstantDeclaration ::=
   # Const Identifier = ConstantExpression LineTerminator
```

See Also

3.1.2 Conditional Compilation Directives | 3.1 Conditional Compilation | #Const Directive (Visual Basic Language Reference) | Declaring Conditional Compilation Constants and Enumerations (Visual Basic Language Concepts)

3.1.2 Conditional Compilation Directives

Conditional compilation directives control conditional compilation and can only reference constant expressions and conditional compilation constants. Each of the constant expressions within a single conditional compilation group is evaluated and converted to the **Boolean** type in textual order from first to last until one of the conditional expressions evaluates to **True**. If an expression is not convertible to **Boolean**, a compile-time error results. Permissive semantics are always used when evaluating conditional compilation constant expressions, regardless of any **Option** directives or compilation environment settings.

All lines enclosed by the group, including nested conditional compilation directives, are disabled except for lines between the statement containing the **True** expression and the next conditional statement of the group, or lines between the **Else** statement and the **End If** statement if an **Else** appears in the group and all of the expressions evaluate to **False**.

In this example, the call to `WriteToLog` in the `Trace` conditional compilation directive is not processed because the surrounding `Debug` conditional compilation directive evaluates to **False**.

```
#Const Debug = False   ' Debugging off
#Const Trace = True    ' Tracing on

Class PurchaseTransaction
    Sub Commit()
#If Debug Then
        CheckConsistency()
#If Trace Then
        WriteToLog(Me.ToString())
#End If
#End If
        CommitHelper()
    End Sub
End Class
```

```
ConditionalIfGroup ::=
   # If ConstantExpression [ Then ] LineTerminator
   [ ConditionalElement+ ]
   [ ConditionalElseIfGroup+ ]
   [ ConditionalElseGroup ]
   # End If LineTerminator
ConditionalElseIfGroup ::=
   # ElseIf ConstantExpression [ Then ] LineTerminator
   [ ConditionalElement+ ]
ConditionalElseGroup ::=
   # Else LineTerminator
   [ ConditionalElement+ ]
```

See Also

3.1.1 Conditional Constant Directives | 3.1 Conditional Compilation | #If...Then...#Else Directives (Visual Basic Language Reference) | Conditional Compilation Overview (Visual Basic Language Concepts)

3.2 External Source Directives

A source file may include external source directives that indicate a mapping between source lines and text external to the source. External source directives have no effect on compilation and may not be nested. For example:

```
Imports System

Module Test
    Sub Main()
#ExternalSource("c:\wwwroot\inetpub\test.aspx", 30)
        Console.WriteLine("In test.aspx")
#End ExternalSource
    End Sub
End Module
```

```
Start ::= [ ExternalSourceElement+ ]
ExternalSourceElement ::= ExternalSourceGroup | LogicalLine
ExternalSourceGroup ::=
   # ExternalSource ( StringLiteral , IntLiteral ) LineTerminator
   [ LogicalLine+ ]
   # End ExternalSource LineTerminator
```

See Also

3.1 Conditional Compilation | 3.3 Region Directives | #ExternalSource Directive (Visual Basic Language Reference)

3.3 Region Directives

Region directives group lines of source code but have no other effect on compilation. The entire group can be collapsed and hidden, or expanded and viewed, in the integrated development environment (IDE). These directives are special in that they can neither start nor terminate within a method body. For example:

```
Module Test
#Region "Startup code – do not edit"
    Sub Main()
    End Sub
#End Region
End Module
```

```
Start ::= [ RegionElement+ ]
RegionElement ::= RegionGroup | LogicalLine
RegionGroup ::=
   # Region StringLiteral LineTerminator
   [ LogicalLine+ ]
   # End Region LineTerminator
```

4. General Concepts

This chapter covers a number of concepts that are required to understand the semantics of the Microsoft Visual Basic .NET language. Many of the concepts should be familiar to Visual Basic programmers or C/C++ programmers, but their precise definitions may differ.

See Also

4.1 Declarations | 4.3 Inheritance | 4.4 Implementation | 4.5 Polymorphism | 4.6 Accessibility | 4.2 Scope | 4.7 Type and Namespace Names | 4.7.1 Qualified Name Resolution | 5. Attributes

4.1 Declarations

A Visual Basic .NET program is made up of named entities. These entities are introduced through *declarations* and represent the "meaning" of the program.

At a top level, *namespaces* are entities that organize other entities, such as nested namespaces and types. *Types* are entities that describe values and define executable code. Types may contain nested types and type members. *Type members* are constants, variables, methods, properties, events, enumeration values, and constructors.

An entity that can contain other entities defines a *declaration space*. Entities are introduced into a declaration space either through declarations or inheritance; the containing declaration space is called the entities' *declaration context*. Declaring an entity in a declaration space in turn defines a new declaration space that can contain further nested entity declarations; thus, the declarations in a program form a hierarchy of declaration spaces.

Except in the case of overloaded type members, it is invalid for declarations to introduce identically named entities of the same kind into the same declaration context. Additionally, a declaration space may never contain different kinds of entities with the same name; for example, a declaration space may never contain a variable and a method by the same name.

The declaration space of a namespace is "open ended," so two namespace declarations with the same fully qualified name contribute to the same declaration space. In the example below, the two namespace declarations contribute to the same declaration space, in this case declaring two classes with the fully qualified names `Data.Customer` and `Data.Order`:

```
Namespace Data
    Class Customer
    End Class
End Namespace

Namespace Data
    Class Order
    End Class
End Namespace
```

Because the two declarations contribute to the same declaration space, a compile-time error would occur if each contained a declaration of a class with the same name.

See Also

4.1.1 Overloading and Signatures | 4.3 Inheritance | 4.4 Implementation | 4.5 Polymorphism | 4.6 Accessibility | 4.2 Scope | 4.7 Type and Namespace Names | 4.7.1 Qualified Name Resolution | 5. Attributes

4.1.1 Overloading and Signatures

The only way to declare identically named entities of the same kind in a declaration space is through *overloading*. Only methods, instance constructors, and properties may be overloaded.

Overloaded type members must possess unique signatures. The signature of a type member consists of the name of the type member and the number and types of the member's parameters.

The following are not part of a member's signature, and hence cannot be overloaded on:

- Modifiers to a type member (for example, **Shared** or **Private**).
- Modifiers to a parameter (for example, **ByVal** or **ByRef**).
- The names of the parameters.
- The return type of a method or the element type of a property.

The following example shows a set of overloaded method declarations along with their signatures. This declaration would not be valid since several of the method declarations have identical signatures.

```
Interface ITest
    Sub F()                              ' Signature is F().
    Sub F(x As Integer)                  ' Signature is F(Integer).
    Sub F(ByRef x As Integer)            ' Signature is F(Integer).
    Sub F(x As Integer, y As Integer)    ' Signature is F(Integer, Integer).
    Function F(s As String) As Integer   ' Signature is F(String).
    Function F(x As Integer) As Integer  ' Signature is F(Integer).
    Sub F(a() As String)                 ' Signature is F(String()).
    Sub F(ParamArray ByVal a() As String) ' Signature is F(String()).
End Interface
```

A method with optional parameters is considered to have multiple signatures, one for each set of parameters that can be passed in by the caller. For example, the following method has three corresponding signatures:

```
Overloads Sub F(ByVal x As Short, _
    ByVal Optional y As Integer = 10, _
    ByVal Optional z As Long = 20)
```

These are the method's signatures:

- F(Short)
- F(Short, Integer)
- F(Short, Integer, Long)

See Also

4.1 Declarations | Overloads (Visual Basic Language Reference) | Procedure Overloading (Visual Basic Language Concepts)

4.2 Scope

The *scope* of an entity's name is the set of all declaration spaces within which it is possible to refer to that name without qualification. In general, the scope of an entity's name is its entire declaration context; however, an entity's declaration may contain nested declarations of entities with the same name. In that case, the nested entity *shadows*, or hides, the outer entity, and access to the shadowed entity is only possible through qualification.

Shadowing through nesting occurs in namespaces or types nested within namespaces, in types nested within other types, and in the bodies of type members. Shadowing through the nesting of declarations always occurs implicitly; no explicit syntax is required.

In the following example, within the `F` method, the instance variable `i` is shadowed by the local variable `i`, but within the `G` method, `i` still refers to the instance variable.

```
Class Test
    Private i As Integer = 0
    Sub F()
        Dim i As Integer = 1
    End Sub

    Sub G()
        i = 1
    End Sub
End Class
```

When a name in an inner scope hides a name in an outer scope, it shadows all overloaded occurrences of that name. In the following example, the call `F(1)` invokes the `F` declared in `Inner` because all outer occurrences of `F` are hidden by the inner declaration. For the same reason, the call `F("Hello")` is in error.

```
Class Outer
    Shared Sub F(i As Integer)
    End Sub

    Shared Sub F(s As String)
    End Sub

    Class Inner
        Shared Sub F(l As Long)
        End Sub

        Sub G()
            F(1) ' Invokes Outer.Inner.F.
            F("Hello") ' Error.
        End Sub
    End Class
End Class
```

See Also

4.1 Declarations | 4.3 Inheritance | 4.4 Implementation | 4.5 Polymorphism | 4.6 Accessibility | 4.7 Type and Namespace Names | 5. Attributes | Scope (Visual Basic Language Concepts)

4.3 Inheritance

An inheritance relationship is one in which one type (the *derived* type) derives from another (the *base* type), such that the derived type's declaration space implicitly contains the accessible nonconstructor type members and nested types of its base type. In the following example, class `A` is the base class of `B`, and `B` is derived from `A`.

```
Class A
End Class

Class B
    Inherits A
End Class
```

Since `A` does not explicitly specify a base class, its base class is implicitly **Object**.

The following are important aspects of inheritance:

- Inheritance is transitive. If type *C* is derived from type *B*, and type *B* is derived from type *A*, type *C* inherits the type members declared in type *B* as well as the type members declared in type *A*.
- A derived type extends, but cannot narrow, its base type. A derived type can add new type members, and it can shadow inherited type members, but it cannot remove the definition of an inherited type member.
- Because an instance of a type contains all of the type members of its base type, a conversion always exists from a derived type to its base type.
- All types must have a base type, except for the type **Object**. Thus, **Object** is the ultimate base type of all types, and all types can be converted to it.
- Circularity in derivation is not permitted. That is, when a type `B` derives from a type `A`, it is an error for type `A` to derive directly or indirectly from type `B`.

The following example produces a compile-time error because the classes circularly depend on each other.

```
Class A
    Inherits B
End Class

Class B
    Inherits C
End Class

Class C
    Inherits A
End Class
```

It is valid for a class to derive from classes that are nested within it or within other classes. In the following example, `A` derives from `B.C` and `B` derives from `A`, but `C` does not derive from `B`.

```
Class A
    Inherits B.C
End Class

Class B
    Inherits A

    Public Class C
    End Class
End Class
```

In the next example, class `B` derives from class `A`, but class `A` does not derive from class `B`.

```
Class A
    Class B
        Inherits A
```

```
    End Class
End Class
```

4.3.1 MustInherit and NotInheritable Classes | 4.3.2 Interfaces and Multiple Inheritance | 4.3.3 Shadowing | 4.1 Declarations | 4.4 Implementation | 4.5 Polymorphism | 4.6 Accessibility | 4.2 Scope | 4.7 Type and Namespace Names | 5. Attributes | Inheritance (Visual Basic Language Concepts)

4.3.1 MustInherit and NotInheritable Classes

A **MustInherit** class is an incomplete type that can act only as a base type. A **MustInherit** class cannot be instantiated, so it is an error to use the **New** operator on one. It is valid to declare variables of **MustInherit** classes; such variables can only be assigned **Nothing** or a value that is of a class derived from the **MustInherit** class.

When a regular class is derived from a **MustInherit** class, the regular class must override all inherited **MustOverride** members. For example:

```
MustInherit Class A
    Public MustOverride Sub F()
End Class

MustInherit Class B
    Inherits A

    Public Sub G()
    End Sub
End Class

Class C
    Inherits B

    Public Overrides Sub F()
    End Sub
End Class
```

The **MustInherit** class `A` introduces a **MustOverride** method `F`. Class `B` introduces an additional method `G`, but does not provide an implementation of `F`. Class `B` must therefore also be declared **MustInherit**. Class `C` overrides `F` and provides an actual implementation. Since there are no outstanding **MustOverride** members in class `C`, it is not required to be **MustInherit**.

A **NotInheritable** class is a class from which another class cannot be derived. **NotInheritable** classes are primarily used to prevent unintended derivation.

In this example, class `B` is in error because it attempts to derive from the **NotInheritable** class `A`. A class can not be marked both **MustInherit** and **NotInheritable**.

```
NotInheritable Class A
End Class

Class B
    ' Error, a class cannot derive from a NotInheritable class.
    Inherits A
End Class
```

4.3.1 MustInherit and NotInheritable Classes | 4.3.2 Interfaces and Multiple Inheritance | 4.3.3 Shadowing | 4.3 Inheritance | MustInherit | NotInheritable (Visual Basic Language Reference) |
Inheritance and the Base Object Class (Visual Basic Language Concepts)

4.3.2 Interfaces and Multiple Inheritance

Unlike other types, which only derive from a single base type, an interface may derive from multiple base interfaces. Because of this, an interface can inherit an identically named type member from different base interfaces. In such a case, the multiply-inherited name is not available in the derived interface, and referring to any of those type members through the derived interface causes a compile-time error, regardless of signatures or overloading. Instead, conflicting type members must be referenced through a base interface name.

In the following example, the first two statements cause compile-time errors because the multiply-inherited member `Count` is not available in interface `IListCounter`:

```
Interface IList
    Property Count() As Integer
End Interface

Interface ICounter
    Sub Count(ByVal i As Integer)
End Interface

Interface IListCounter
    Inherits IList
    Inherits ICounter
End Interface

Module Test
    Sub F(ByVal x As IListCounter)
        x.Count(1)                  ' Error, Count is not available.
        x.Count = 1                 ' Error, Count is not available.
        CType(x, IList).Count = 1   ' Ok, invokes IList.Count.
        CType(x, ICounter).Count(1) ' Ok, invokes ICounter.Count.
    End Sub
End Module
```

As illustrated by the example, the ambiguity is resolved by casting `x` to the appropriate base interface type. Such casts have no run-time costs; they merely consist of viewing the instance as a less-derived type at compile time.

When a single type member is inherited from the same base interface through multiple paths, the type member is treated as if it were only inherited once. In other words, the derived interface only contains one instance of each type member inherited from a particular base interface. For example:

```
Interface IBase
    Sub F(ByVal i As Integer)
End Interface

Interface ILeft
    Inherits IBase
End Interface

Interface IRight
    Inherits IBase
End Interface

Interface IDerived
    Inherits ILeft, IRight
End Interface

Class Derived
    Implements IDerived

    ' Only have to implement F once.
    Sub F(ByVal i As Integer) Implements IDerived.F
    End Sub
End Class
```

If a type member name is shadowed in one path through the inheritance hierarchy but not through all of them, the name is still unavailable in derived interfaces. In the following example, the `IBase.F` member is shadowed by the `ILeft.F` member, but is not shadowed in `IRight`:

```
Interface IBase
    Sub F(ByVal i As Integer)
End Interface

Interface ILeft
    Inherits IBase
    Shadows Sub F(ByVal i As Integer)
End Interface

Interface IRight
    Inherits IBase
    Sub G()
End Interface

Interface IDerived
    Inherits ILeft, IRight
End Interface

Class Test
    Sub H(ByVal d As IDerived)
        d.F(1)                  ' Error: F not available in IDerived.
        CType(d, IBase).F(1)    ' Invokes IBase.F.
        CType(d, ILeft).F(1)    ' Invokes ILeft.F.
        CType(d, IRight).F(1)   ' Invokes IBase.F.
    End Sub
End Class
```

The invocation `d.F(1)` produces an error because in `IDerived` the name `F` is visible both from `ILeft.F` and from `IBase.F` through `IRight`.

See Also

4.3.1 MustInherit and NotInheritable Classes | 4.3.3 Shadowing | 4.3 Inheritance

4.3.3 Shadowing

A derived type shadows the name of an inherited type member by redeclaring it. Shadowing a name does not remove the inherited type members with that name; it merely makes all of the inherited type members with that name unavailable in the derived class. The shadowing declaration may be any type of entity.

Entities than can be overloaded can choose one of two forms of shadowing. *Shadowing by name* is specified using the **Shadows** keyword. An entity that shadows by name hides everything by that name in the base class, including all overloads. *Shadowing by name and signature* is specified using the **Overloads** keyword. An entity that shadows by name and signature hides everything by that name with the same signature as the entity. For example:

```
Imports System

Class Base
    Sub F()
    End Sub

    Sub F(ByVal i As Integer)
    End Sub

    Sub G()
    End Sub

    Sub G(ByVal i As Integer)
    End Sub
End Class

Class Derived
    Inherits Base

    ' Only hides F(Integer).
    Overloads Sub F(ByVal i As Integer)
    End Sub

    ' Hides G() and G(Integer).
    Shadows Sub G(ByVal i As Integer)
    End Sub
End Class

Module Test
    Sub Main()
        Dim x As Derived = New Derived()

        x.F() ' Calls Base.F().
        x.G() ' Error: No such method.
    End Sub
End Module
```

A shadowing method or property that does not specify **Shadows** or **Overloads** assumes **Shadows**. If one member of a set of overloaded entities specifies the **Shadows** or **Overloads** keyword, they all must specify it. The **Shadows** and **Overloads** keywords cannot be specified at the same time.

It is valid to shadow the name of a type member that has been multiply-inherited through interface inheritance (and which is thereby unavailable), thus making the name available in the derived interface.

For example:

```
Interface ILeft
    Sub F()
End Interface

Interface IRight
    Sub F()
End Interface
```

```
Interface ILeftRight
    Inherits ILeft, IRight
    Shadows Sub F()
End Interface

Module Test
    Sub G(ByVal i As ILeftRight)
        i.F() ' Calls ILeftRight.F.
        CType(i, ILeft).F() ' Calls ILeft.F.
        CType(i, IRight).F() ' Calls IRight.F.
    End Sub
End Module
```

Because methods are allowed to shadow inherited methods, it is possible for a class to contain several **Overridable** methods with the same signature. This does not present an ambiguity problem, since only the most-derived method is visible. In the following example, the `C` and `D` classes contain two **Overridable** methods with the same signature:

```
Imports System

Class A
    Public Overridable Sub F()
        Console.WriteLine("A.F")
    End Sub
End Class

Class B
    Inherits A

    Public Overrides Sub F()
        Console.WriteLine("B.F")
    End Sub
End Class

Class C
    Inherits B

    Public Shadows Overridable Sub F()
        Console.WriteLine("C.F")
    End Sub
End Class

Class D
    Inherits C

    Public Overrides Sub F()
        Console.WriteLine("D.F")
    End Sub
End Class

Module Test
    Sub Main()
        Dim d As New D()
        Dim a As A = d
        Dim b As B = d
        Dim c As C = d
        a.F()
        b.F()
        c.F()
        d.F()
    End Sub
End Module
```

There are two **Overridable** methods here: one introduced by class `A` and the one introduced by class `C`. The method introduced by class `C` hides the method inherited from class `A`. Thus, the **Overrides** declaration in class `D` overrides the method introduced by class `C`, and it is not possible for class `D` to override the method introduced by class `A`. The example produces the output:

```
B.F
B.F
D.F
D.F
```

It is possible to invoke the hidden **Overridable** method by accessing an instance of class `D` through a less-derived type in which the method is not hidden.

It is not valid to shadow a **MustOverride** method, because in most cases this would make the class unusable. For example:

```
MustInherit Class Base
    Public MustOverride Sub F()
End Class

MustInherit Class Derived
    Inherits Base

    Public Shadows Sub F()
    End Sub
End Class

Class MoreDerived
    Inherits Derived

    ' Error: MustOverride method Base.F is not overridden.
End Class
```

In this case, the class `MoreDerived` is required to override the **MustOverride** method `Base.F`, but because the class `Derived` shadows `Base.F`, this is not possible. There is no way to declare a valid descendent of `Derived`.

In contrast to shadowing a name from an outer scope, shadowing an accessible name from an inherited scope causes a warning to be reported, as in the following example:

```
Class Base
    Public Sub F()
    End Sub

    Private Sub G()
    End Sub
End Class

Class Derived
    Inherits Base

    Public Sub F() ' Warning: shadowing an inherited name.
    End Sub

    Public Sub G() ' No warning, Base.G is not accessible here.
    End Sub
End Class
```

The declaration of method `F` in class `Derived` causes a warning to be reported. Shadowing an inherited name is specifically not an error, since that would preclude separate evolution of base classes. For example, the above situation might have come about because a later version of class `Base` introduced a method `F` that was not present in an earlier version of the class. Had the above situation been an error, *any* change made to a base class in a separately versioned class library could potentially cause derived classes to become invalid.

The warning caused by shadowing an inherited name can be eliminated through use of the **Shadows** or **Overloads** modifier:

```
Class Base
    Public Sub F()
    End Sub
End Class
```

```
Class Derived
    Inherits Base

    Public Shadows Sub F() 'OK.
    End Sub
End Class
```

The **Shadows** modifier indicates the intention to shadow the inherited member. It is not an error to specify the **Shadows** or **Overloads** modifier if there is no type member name to shadow.

A declaration of a new member shadows an inherited member only within the scope of the new member, as in the following example:

```
Class Base
    Public Shared Sub F()
    End Sub
End Class

Class Derived
    Inherits Base

    Private Shared Shadows Sub F() ' Shadows Base.F in class Derived only.
    End Sub
End Class

Class MoreDerived
    Inherits Derived

    Shared Sub G()
        F() ' Invokes Base.F.
    End Sub
End Class
```

In the example above, the declaration of method `F` in class `Derived` shadows the method `F` that was inherited from class `Base`, but since the new method `F` in class `Derived` has **Private** access, its scope does not extend to class `MoreDerived`. Thus, the call `F()` in `MoreDerived.G` is valid and will invoke `Base.F`. In the case of overloaded type members, the entire set of overloaded type members is treated as if they all had the most permissive access for the purposes of shadowing.

```
Class Base
    Public Sub F()
    End Sub
End Class

Class Derived
    Inherits Base

    Private Shadows Sub F()
    End Sub

    Public Shadows Sub F(ByVal i As Integer)
    End Sub
End Class

Class MoreDerived
    Inherits Derived

    Public Sub G()
        F()   ' Error. No accessible member with this signature.
    End Sub
End Class
```

In this example, even though the declaration of `F()` in `Derived` is declared with **Private** access, the overloaded `F(Integer)` is declared with **Public** access. Therefore, for the purpose of shadowing, the name `F` in `Derived` is treated as if it was **Public**, so both methods shadow `F` in `Base`.

4.4 Implementation

An *implementation* relationship exists when a type declares that it implements an interface and the type implements all the type members of the interface. A type that implements a particular interface is convertible to that interface. Interfaces cannot be instantiated, but it is valid to declare variables of interfaces; such variables can only be assigned a value that is of a class that implements the interface. For example:

```
Interface ITestable
    Function Test(ByVal Value As Byte) As Boolean
End Interface

Class TestableClass
    Implements ITestable

    Function Test(ByVal Value As Byte) _
             As Boolean Implements ITestable.Test
        Return (Value > 128)
    End Function
End Class

Module Test
    Sub F()
        Dim x As ITestable = New TestableClass
        Dim b As Boolean

        b = x.Test(34)
    End Sub
End Module
```

A type implementing an interface with multiply-inherited type members must still implement those methods, even though they cannot be accessed directly from the derived interface being implemented. For example:

```
Interface ILeft
    Sub Test()
End Interface

Interface IRight
    Sub Test()
End Interface

Interface ILeftRight
    Inherits ILeft, IRight
End Interface

Class LeftRight
    Implements ILeftRight

    ' Has to reference ILeft explicitly.
    Sub TestLeft() Implements ILeft.Test
    End Sub

    ' Has to reference IRight explicitly.
    Sub TestRight() Implements IRight.Test
    End Sub

    ' This causes an error because Test is not available in ILeftRight.
    Sub TestLeftRight() Implements ILeftRight.Test
    End Sub
End Class
```

Even **MustInherit** classes must provide implementations of all the members of implemented interfaces; however, they can defer implementation of these methods by declaring them as **MustOverride**. For example:

```
Interface ITest
```

```
    Sub Test1()
    Sub Test2()
End Interface

MustInherit Class TestBase
    Implements ITest

    ' Provides an implementation.
    Sub Test1() Implements ITest.Test1
    End Sub

    ' Defers implementation.
    MustOverride Sub Test2() Implements ITest.Test2
End Class

Class TestDerived
    Inherits TestBase

    ' Have to implement MustOverride method.
    Overrides Sub Test2()
    End Sub
End Class
```

4.4.1 Implementing Methods

A type *implements* a type member of an implemented interface by supplying a method with an **Implements** clause. The two type members must have the same number of parameters, and all of the types and modifiers of the parameters must match, including the default value of optional parameters. For example:

```
Interface ITest
    Sub F(ByRef x As Integer)
    Sub G(ByVal Optional y As Integer = 20)
    Sub H(ByVal Paramarray z() As Integer)
End Interface

Class Test
    Implements ITest

    ' Error: ByRef/ByVal mismatch.
    Sub F(ByVal x As Integer) Implements ITest.F
    End Sub

    ' Error: Defaults do not match.
    Sub G(ByVal Optional y As Integer = 10) Implements ITest.G
    End Sub

    ' Error: Paramarray does not match.
    Sub H(ByVal z() As Integer) Implements ITest.H
    End Sub
End Class
```

A single method may implement any number of interface type members if they all meet the above criteria. For example:

```
Interface ITest
    Sub F(ByVal i As Integer)
    Sub G(ByVal i As Integer)
End Interface

Class Test
    Implements ITest

    Sub F(ByVal i As Integer) Implements ITest.F, ITest.G
    End Sub
End Class
```

A derived type may not implement an interface type member that is already implemented by any of its base types; however, when an interface method is implemented using an overridable method in a base type, a derived type may override the overridable method and alter the implementation of the interface. For example:

```
Interface ITest
    Sub Test1()
    Sub Test2()
End Interface

Class Base
    Implements ITest

    Public Sub Test1() Implements ITest.Test1
    End Sub

    Public Overridable Sub Test2() Implements ITest.Test2
    End Sub
End Class

Class Derived
    Inherits Base
```

```
    ' Error: ITest.Test1 already implemented.
    Public Sub Test1() Implements ITest.Test1
    End Sub

    ' Valid: Overrides base implementation.
    Public Overrides Sub Test2()
    End Sub
End Class
```

A derived type may implement an interface whose base interfaces are implemented by the derived type's base types. In that case, the derived type only implements the interface's type members not already implemented by the base types. For example:

```
Interface IBase
    Sub Base()
End Interface

Interface IDerived
    Inherits IBase

    Sub Derived()
End Interface

Class Base
    Implements IBase

    Public Sub Base() Implements IBase.Base
    End Sub
End Class

Class Derived
    Inherits Base
    Implements IDerived

    ' Error: IBase.Base already implemented by Base.
    Public Sub Base() Implements IDerived.Base
    End Sub

    ' Valid: IDerived.Derived not implemented by Base.
    Public Sub Derived() Implements IDerived.Derived
    End Sub
End Class
```

4.5 Polymorphism | Implements Statement (Visual Basic Language Reference) |
Implements Keyword (Visual Basic Language Concepts)

4.5 Polymorphism

Polymorphism provides the ability to vary the implementation of a method or property. With polymorphism, the same method or property can perform different actions depending on the run-time type of the instance that invokes it. Methods or properties that are polymorphic are called *overridable*. By contrast, the implementation of a non-overridable method or property is invariant; the implementation is the same whether the method or property is invoked on an instance of the class in which it is declared or an instance of a derived class. When a non-overridable method or property is invoked, the compile-time type of the instance is the determining factor. For example:

```
Class Base
    Public Overridable Property X() As Integer
        Get
        End Get

        Set
        End Set
    End Property
End Class

Class Derived
    Public Overrides Property X() As Integer
        Get
        End Get

        Set
        End Set
    End Property
End Class

Module Test
    Sub F()
        Dim Z As Base

        Z = New Base()
        Z.X = 10            ' Calls Base.X
        Z = New Derived()
        Z.X = 10            ' Calls Derived.X
    End Sub
End Module
```

An overridable method may also be **MustOverride**, which means that it provides no method body and must be overridden. **MustOverride** methods are only allowed in **MustInherit** classes.

In the following example, the class `Shape` defines the abstract notion of a geometrical shape object that can paint itself:

```
MustInherit Public Class Shape
    Public MustOverride Sub Paint(ByVal g As Graphics, _
                                  ByVal r As Rectangle)
End Class

Public Class Ellipse
    Inherits Shape

    Public Overrides Sub Paint(ByVal g As Graphics, ByVal r As Rectangle)
        g.drawEllipse(r)
    End Sub
End Class

Public Class Box
    Inherits Shape

    Public Overrides Sub Paint(ByVal g As Graphics, ByVal r As Rectangle)
        g.drawRect(r)
    End Sub
End Class
```

The `Paint` method is **MustOverride** because there is no meaningful default implementation. The `Ellipse` and `Box` classes are concrete `Shape` implementations. Because these classes are not **MustInherit**, they are required to override the `Paint` method and provide an actual implementation.

It is an error for a base access to reference a **MustOverride** method, as the following example demonstrates:

```
Class A
    Public MustOverride Sub F()
End Class

Class B
    Inherits A

    Public Overrides Sub F()
        MyBase.F() ' Error, MyBase.F is MustOverride.
    End Sub
End Class
```

An error is reported for the `MyBase.F()` invocation because it references a **MustOverride** method.

4.5.1 Overriding Methods

A type may *override* an inherited overridable method by declaring a method with the same name and signature, and marking the declaration with the **Overrides** modifier. Whereas an **Overridable** method declaration introduces a new method, an **Overrides** method declaration replaces the inherited implementation of the method.

An overriding method may also be declared **NotOverridable**, which prevents any further overriding of the method in derived types. In effect, **NotOverridable** methods become non-overridable in any further derived classes.

Consider the following example:

```
Imports System

Class A
    Public Overridable Sub F()
        Console.WriteLine("A.F")
    End Sub

    Public Overridable Sub G()
        Console.WriteLine("A.G")
    End Sub
End Class

Class B
    Inherits A

    Public Overrides NotOverridable Sub F()
        Console.WriteLine("B.F")
    End Sub

    Public Overrides Sub G()
        Console.WriteLine("B.G")
    End Sub
End Class

Class C
    Inherits B

    Public Overrides Sub G()
        Console.WriteLine("C.G")
    End Sub
End Class
```

In the example, class `B` provides two **Overrides** methods: a method `F` that has the **NotOverridable** modifier and a method `G` that does not. Use of the **NotOverridable** modifier prevents class `C` from further overriding method `F`.

A compile-time error occurs unless all of the following are true of an overriding method:

- The declaration context contains an accessible inherited method with the same signature as the overriding method.
- The inherited method being overridden is overridable. In other words, the inherited method being overridden is not **Shared** or **NotOverridable**.
- The accessibility domain of the method being declared is the same as the accessibility domain of the inherited method being overridden. There is one exception: a **Protected Friend** method must be overridden by a **Protected** method if the two methods are not in the same program.
- The parameters of the overriding method match the overridden method's parameters in regards to usage of the **ByVal**, **ByRef**, **ParamArray,** and **Optional** modifiers, including the values provided for optional parameters.

An override declaration can access the overridden base method using a base access, as in the following example:

```
Imports System

Class Base
    Private x As Integer
```

```
    Public Overridable Sub PrintVariables()
        Console.WriteLine("x = " & x)
    End Sub
End Class

Class Derived
    Inherits Base

    Private y As Integer

    Public Overrides Sub PrintVariables()
        MyBase.PrintVariables()
        Console.WriteLine("y = " & y)
    End Sub
End Class
```

In the example, the invocation of `MyBase.PrintVariables()` in class `Derived` invokes the `PrintVariables` method declared in class `Base`. A base access disables the overridable invocation mechanism and simply treats the base method as a non-overridable method. Had the invocation in `Derived` been written `CType(Me, Base).PrintVariables()`, it would recursively invoke the `PrintVariables` method declared in `Derived`, not the one declared in `Base`.

Only when it includes an **Overrides** modifier can a method override another method. In all other cases, a method with the same signature as an inherited method simply shadows the inherited method, as in the example below:

```
Class Base
    Public Overridable Sub F()
    End Sub
End Class

Class Derived
    Inherits Base

    Public Overridable Sub F() ' Warning, shadowing inherited F().
    End Sub
End Class
```

In the example, the method `F` in class `Derived` does not include an **Overrides** modifier and therefore does not override method `F` in class `Base`. Rather, method `F` in class `Derived` shadows the method in class `Base`, and a warning is reported because the declaration does not include a **Shadows** or **Overloads** modifier.

In the following example, method `F` in class `Derived` shadows the overridable method `F` inherited from class `Base`:

```
Class Base
    Public Overridable Sub F()
    End Sub
End Class

Class Derived
    Inherits Base

    Private Shadows Sub F() ' Shadows Base.F within Derived.
    End Sub
End Class

Class MoreDerived
    Inherits Derived

    Public Overrides Sub F() ' Ok, overrides Base.F.
    End Sub
End Class
```

Since the new method `F` in class `Derived` has **Private** access, its scope only includes the class body of `Derived` and does not extend to class `MoreDerived`. The declaration of method `F` in class `MoreDerived` is therefore permitted to override the method `F` inherited from class `Base`.

When an **Overridable** method is invoked, the most derived implementation of the instance method is called, based on the type of

the instance, regardless of whether the call is to the method in the base class or the derived class. The most derived implementation of an **Overridable** method `M` with respect to a class `R` is determined as follows:

- If `R` contains the introducing **Overridable** declaration of `M`, this is the most derived implementation of `M`.
- Otherwise, if `R` contains an override of `M`, this is the most derived implementation of `M`.
- Otherwise, the most derived implementation of `M` is the same as that of the direct base class of `R`.

4.5 Polymorphism | 4.1 Declarations | 4.6 Accessibility | Overrides (Visual Basic Language Reference) | Overriding Properties and Methods (Visual Basic Language Concepts)

4.6 Accessibility

A declaration specifies the *accessibility* of the entity it declares. An entity's accessibility does not change the scope of an entity's name. The *accessibility domain* of a declaration is the set of all declaration spaces in which the declared entity is accessible.

The five access types are **Public**, **Protected**, **Friend**, **Protected Friend**, and **Private**. **Public** is the most permissive access type, and the four other types are all subsets of **Public**. The least permissive access type is **Private**, and the four other access types are all supersets of **Private**.

The access type for a declaration is specified via an optional access modifier, which can be **Public**, **Protected**, **Friend**, **Private**, or the combination of **Protected** and **Friend**. If no access modifier is specified, the default access type depends on the declaration context; the permitted access types also depend on the declaration context.

- Entities declared with the **Public** modifier have **Public** access. There are no restrictions on the use of **Public** entities.
- Entities declared with the **Protected** modifier have **Protected** access. **Protected** access can only be specified on members of classes (both regular type members and nested classes) or on **Overridable** members of standard modules and structures (which must, by definition, be inherited from **System.Object** or **System.ValueType**). A **Protected** member is accessible to a derived class, provided that either the member is not an instance member, or the access takes place through an instance of the derived class. **Protected** access is not a superset of **Friend** access.
- Entities declared with the **Friend** modifier have **Friend** access. An entity with **Friend** access is accessible only within the program that contains the entity declaration.
- Entities declared with the **Protected Friend** modifiers have the union of **Protected** and **Friend** access.
- Entities declared with the **Private** modifier have **Private** access. A **Private** entity is accessible only within its declaration context, including any nested entities.

The accessibility in a declaration does not depend on the accessibility of the declaration context. For example, a type declared with **Private** access may contain a type member with **Public** access.

The following code demonstrates various accessibility domains:

```
Public Class A
    Public Shared X As Integer
    Friend Shared Y As Integer
    Private Shared Z As Integer
End Class

Friend Class B
    Public Shared X As Integer
    Friend Shared Y As Integer
    Private Shared Z As Integer

    Public Class C
        Public Shared X As Integer
        Friend Shared Y As Integer
        Private Shared Z As Integer
    End Class

    Private Class D
        Public Shared X As Integer
        Friend Shared Y As Integer
        Private Shared Z As Integer
    End Class
End Class
```

The classes and members have the following accessibility domains:

- The accessibility domain of `A` and `A.X` is unlimited.
- The accessibility domain of `A.Y`, `B`, `B.X`, `B.Y`, `B.C`, `B.C.X`, and `B.C.Y` is the containing program.
- The accessibility domain of `A.Z` is `A`.
- The accessibility domain of `B.Z` and `B.D` is `B`, including `B.C` and `B.D`.
- The accessibility domain of `B.C.Z` is `B.C`.
- The accessibility domain of `B.D.X`, `B.D.Y`, and `B.D.Z` is `B.D`.

As the example illustrates, the accessibility domain of a member is never larger than that of a containing type. For example, even though all `X` members have **Public** declared accessibility, all but `A.X` have accessibility domains that are constrained by a containing type.

Access to **Protected** instance members must be through an instance of the derived type so that unrelated types cannot gain access to each other's protected members. For example:

```
Public Class User
    Protected Password As String
End Class

Public Class Employee
    Inherits User
End Class

Public Class Guest
    Inherits User

    Public Function GetPassword(ByVal U As User) As String
        ' Error: protected access has to go through derived type.
        Return U.Password
    End Function
End Class
```

In the above example, the class `Guest` only has access to the protected `Password` field if it is qualified with an instance of `Guest`. This prevents `Guest` from gaining access to the `Password` field of an `Employee` object simply by casting it to `User`.

```
AccessModifier ::= Public | Protected | Friend | Private
```

4.1 Declarations | 4.3 Inheritance | 4.4 Implementation | 4.5 Polymorphism | 4.2 Scope | 4.7 Type and Namespace Names | 4.7.1 Qualified Name Resolution | 5. Attributes | Accessibility (Visual Basic Language Concepts)

4.6.1 Constituent Types

The *constituent types* of a declaration are the types that are referenced by the declaration. For example, the type of a constant, the return type of a method and the parameter types of a constructor are all constituent types. The accessibility domain of a constituent type of a declaration must be the same as or a superset of the accessibility domain of the declaration itself. For example:

```
Public Class X
    Private Class Y
    End Class

    ' Error: Exposing private class Y outside of X.
    Public Function Z() As Y
    End Function

    ' Valid: Not exposing outside of X.
    Private Function A() As Y
    End Function
End Class

Private Class B
    Private Class C
    End Class

    ' Error: Exposing private class Y outside of B.
    Public Function D() As C
    End Function
End Class
```

4.7 Type and Namespace Names

Many language constructs require a namespace or type to be specified; these can be specified by using a qualified form of the namespace or type's name. A *qualified name* consists of a series of identifiers separated by periods; the identifier on the right side of a period is resolved in the declaration space specified by the identifier on the left side of the period.

The *fully qualified name* of a namespace or type is a qualified name that contains the name of all containing namespaces and types. In other words, the fully qualified name of a namespace or type is `N.T`, where `T` is the name of the entity and `N` is the fully qualified name of its containing entity.

The example below shows several namespace and type declarations together with their associated fully qualified names in in-line comments.

```
Class A            ' A.
End Class

Namespace X        ' X.
    Class B        ' X.B.
        Class C    ' X.B.C.
        End Class
    End Class

    Namespace Y    ' X.Y.
        Class D    ' X.Y.D.
        End Class
    End Namespace
End Namespace

Namespace X.Y      ' X.Y.
    Class E        ' X.Y.E.
    End Class
End Namespace
```

Because other languages may introduce types and namespaces that match keywords in the language, Visual Basic .NET recognizes keywords to be part of a qualified name as long as they follow a period. Keywords used in this way are treated as identifiers. For example, the qualified identifier `X.Default.Class` is a valid qualified identifier, while `Default.Class` is not.

```
QualifiedIdentifier ::=
   Identifier |
   QualifiedIdentifier . IdentifierOrKeyword
NamespaceOrTypeName ::= QualifiedIdentifier
```

4.7.1 Qualified Name Resolution | 4.1 Declarations | 4.3 Inheritance | 4.4 Implementation | 4.5 Polymorphism | 4.6 Accessibility | 4.2 Scope | 5. Attributes | Namespace Statement (Visual Basic Language Reference) | Namespaces (Visual Basic Language Concepts)

4.7.1 Qualified Name Resolution

Given a qualified namespace or type name of the form `N.R`, where `R` is the rightmost identifier in the qualified name, the following steps describe how to determine to which namespace or type the qualified name refers:

1. Resolve `N`, which may be either a qualified or unqualified name.
2. If resolution of `N` fails or does not resolve to a namespace or type, a compile-time error occurs. If `R` matches the name of a namespace or type in `N`, then the qualified name refers to that namespace or type.
3. If `N` contains one or more standard modules, and `R` matches the name of a type in exactly one standard module, then the qualified name refers to that type. If `R` matches the name of types in more than one standard module, a compile-time error occurs.
4. Otherwise, a compile-time error occurs.

> **Note** An implication of this resolution process is that type members do not shadow namespaces or types when resolving namespace or type names.

See Also

4.7 Type and Namespace Names | 11.12.3 Operator Resolution | 11.8.1 Overloaded Method Resolution

4.7.2 Unqualified Name Resolution

Given an unqualified name `R`, the following steps describe how to determine to which namespace or type an unqualified name refers:

1. For each nested type containing the name reference, starting from the innermost type and going to the outermost, if `R` matches the name of an accessible nested type in the current type, then the unqualified name refers to that type.
2. For each nested namespace containing the name reference, starting from the innermost namespace and going to the outermost namespace, do the following:
   a. If `R` matches the name of an accessible type or nested namespace in the current namespace, then the unqualified name refers to that type or nested namespace.
   b. If the namespace contains one or more accessible standard modules, and `R` matches the name of an accessible nested type in exactly one standard module, then the unqualified name refers to that nested type. If `R` matches the name of accessible nested types in more than one standard module, a compile-time error occurs.
3. If the source file has one or more import aliases, and `R` matches the name of one of them, then the unqualified name refers to that import alias.
4. If the source file containing the name reference has one or more imports:
   a. If `R` matches the name of a namespace or an accessible type in exactly one import, then the unqualified name refers to that namespace or type. If `R` matches the name of a namespace or accessible type members in more than one import and all are not the same entity, a compile-time error occurs.
   b. If the imports contain one or more accessible standard modules, and `R` matches the name of an accessible nested type in exactly one standard module, then the unqualified name refers to that type. If `R` matches the name of accessible nested types in more than one standard module, a compile-time error occurs.
5. If the compilation environment defines one or more import aliases, and `R` matches the name of one of them, then the unqualified name refers to that import alias.
6. If the compilation environment defines one or more imports:
   a. If `R` matches the name of a namespace or an accessible type in exactly one import, then the unqualified name refers to that namespace or type. If `R` matches the name of namespace or an accessible type member in more than one import, a compile-time error occurs.
   b. If the imports contain one or more accessible standard modules, and `R` matches the name of an accessible nested type in exactly one standard module, then the unqualified name refers to that type. If `R` matches the name of accessible nested types in more than one standard module, a compile-time error occurs.
7. Otherwise, a compile-time error occurs.

> **Note** An implication of this resolution process is that type members do not shadow namespaces or types when resolving namespace or type names.

4.8 Variables

A *variable* represents a storage location. Every variable has a type that determines what values can be stored in the variable. Because Visual Basic .NET is a type-safe language, every variable in a program has a type and the language guarantees that values stored in variables are always of the appropriate type. Variables are always initialized to the default value of their type before any reference to the variable can be made. It is not possible to access uninitialized memory.

4. General Concepts | 4.1 Declarations | 4.2 Scope | 4.6 Accessibility

5. Attributes

The Visual Basic .NET language enables the programmer to specify modifiers on declarations, which represent information about the entities being declared. For example, affixing a class method with the modifiers **Public**, **Protected**, **Friend**, **Protected Friend**, or **Private** specifies its accessibility.

In addition to the modifiers defined by the language, Visual Basic .NET also enables programmers to create new modifiers, called *attributes*, and to use them when declaring new entities. These new modifiers, which are defined through the declaration of attribute classes, are then assigned to entities through *attribute blocks*.

> **Note** Attributes may be retrieved at run time through the .NET Framework's reflection APIs. These APIs are outside the scope of this specification.

For instance, a framework might define a **Help** attribute that can be placed on program elements such as classes and methods to provide a mapping from program elements to documentation, as the following example demonstrates:

```
Imports System

<AttributeUsage(AttributeTargets.All)> _
Public Class HelpAttribute
    Inherits Attribute

    Public Sub New(ByVal UrlValue As String)
        Me.UrlValue = UrlValue
    End Sub

    Public Topic As String
    Private UrlValue As String

    Public ReadOnly Property Url() As String
        Get
            Return UrlValue
        End Get
    End Property
End Class
```

The example defines an attribute class named **HelpAttribute**, or **Help** for short, that has one positional parameter (`UrlValue`) and one named argument (`Topic`).

The next example shows several uses of the attribute:

```
<Help("http://www.example.com/.../Class1.htm")> _
Public Class Class1
    <Help("http://www.example.com/.../Class1.htm", Topic := "F")> _
        Public Sub F()
    End Sub
End Class
```

The next example checks to see if `Class1` has a **Help** attribute, and writes out the associated `Topic` and `Url` values if the attribute is present.

```
Imports System

Module Test
    Sub Main()
        Dim type As Type = GetType(Class1)
        Dim arr() As Object() = _
            type.GetCustomAttributes(GetType(HelpAttribute), True)

        If arr.Length = 0 Then
            Console.WriteLine("Class1 has no Help attribute.")
        Else
            Dim ha As HelpAttribute = CType(arr(0), HelpAttribute)
            Console.WriteLine("Url = " & ha.Url & "Topic = " & ha.Topic)
```

```
        End If
    End Sub
End Module
```

5.1 Attribute Classes

An *attribute class* is a class that derives from **System.Attribute** and is not **MustInherit**. The attribute class must have a **System.AttributeUsage** attribute that declares what the attribute is valid on, whether it may be used multiple times in a declaration, and whether it is inherited. The following example defines an attribute class named `SimpleAttribute` that can be placed on class declarations and interface declarations:

```
Imports System

<AttributeUsage(AttributeTargets.Class Or AttributeTargets.Interface)> _
Public Class SimpleAttribute
    Inherits System.Attribute
End Class
```

The next example shows a few uses of the `Simple` attribute. Although the attribute class is named `SimpleAttribute`, uses of this attribute may omit the *Attribute* suffix, thus shortening the name to `Simple`:

```
<Simple()> Class Class1
End Class
<Simple()> Interface Interface1
End Interface
```

The **System.AttributeUsage** attribute has a variable initializer, `AllowMultiple`, which specifies whether the indicated attribute can be specified more than once for a given declaration. If `AllowMultiple` for an attribute is **True**, it is a *multiple-use attribute class*, and can be specified more than once on a declaration. If `AllowMultiple` for an attribute is **False** or unspecified for an attribute, it is a *single-use attribute class*, and can be specified at most once on a declaration.

The following example defines a multiple-use attribute class named `AuthorAttribute`:

```
Imports System

<AttributeUsage(AttributeTargets.Class, AllowMultiple := True)> _
Public Class AuthorAttribute
    Inherits System.Attribute

    Public Sub New(ByVal Value As String)
    End Sub

    Public ReadOnly Property Value() As String
        Get
        End Get
    End Property
End Class
```

The example shows a class declaration with two uses of the `Author` attribute:

```
<Author("Maria Hammond"), Author("Ramesh Meyyappan")> _
Class Class1
End Class
```

The **System.AttributeUsage** attribute has a public instance variable, `Inherited`, that specifies whether the attribute, when specified on a base type, is also inherited by types that derive from this base type. If the `Inherited` public instance variable is not initialized, a default value of **False** is used. Properties and events do not inherit attributes, although the methods defined by properties and events do. Interfaces do not inherit attributes.

If a single-use attribute is both inherited and specified on a derived type, the attribute specified on the derived type overrides the inherited attribute. If a multiple-use attribute is both inherited and specified on a derived type, both attributes are specified on the derived type. For example:

```
Imports System
```

```
<AttributeUsage(AttributeTargets.Class, AllowMultiple := True, _
                Inherited := True > _
Class MultiUseAttribute
    Inherits System.Attribute

    Public Sub New(ByVal Value As Boolean)
    End Sub
End Class

<AttributeUsage(AttributeTargets.Class, Inherited := True)> _
Class SingleUseAttribute
    Inherits Attribute

    Public Sub New(ByVal Value As Boolean)
    End Sub
End Class

<SingleUse(True), MultiUse(True)> Class Base
End Class

' Derived has three attributes defined on it: SingleUse(False),
' MultiUse(True) and MultiUse(False)
<SingleUse(False), MultiUse(False)> _
Class Derived
    Inherits Base
End Class
```

The positional parameters of the attribute are defined by the parameters of the public constructors of the attribute class. Positional parameters must be **ByVal** and may not specify **ByRef**, **Optional** or **Paramarray**. Public instance variables and properties are defined by public read-write properties or instance variables of the attribute class. The types that can be used in positional parameters and public instance variables and properties are restricted to attribute types. A type is an attribute type if it is one of the following:

- Any primitive type except for **Date** and **Decimal**.
- The type **System.Type**.
- An enumerated type, provided that it and the types in which it is nested (if any) have **Public** accessibility.

See Also

5.2 Attribute Blocks | 5.2.1 Attribute Names | 5.2.2 Attribute Arguments

5.2 Attribute Blocks

Attributes are specified in *attribute blocks*. Each attribute block is delimited by angle brackets ("< >"), with multiple attributes specified in a comma-separated list. The order in which attributes are specified is not significant. For example, the attribute blocks `<A, B>` and `<B, A>` are equivalent.

An attribute may not be specified on a kind of declaration it does not support, and single-use attributes may not be specified more than once in an attribute block. The example below causes errors both because it attempts to use `HelpString` on the interface `Interface1` and more than once on the declaration of `Class1`.

```
Imports System

<AttributeUsage(AttributeTargets.Class)> _
Public Class HelpStringAttribute
    Inherits System.Attribute

    Private InternalValue As String

    Public Sub New(ByVal Value As String)
        Me.InternalValue = Value
    End Sub

    Public ReadOnly Property Value() As String
        Get
            Return InternalValue
        End Get
    End Property
End Class

' Error: HelpString only applies to classes.
<HelpString("Description of Interface1")> _
Interface Interface1
    Sub Sub1()
End Interface

' Error: HelpString is single-use.
<HelpString("Description of Class1"), _
    HelpString("Another description of Class1")> _
Public Class Class1
End Class
```

An attribute consists of an optional attribute modifier, an attribute name, an optional list of positional arguments, and variable/property initializers. If there are no parameters or initializers, the parentheses may be omitted. If an attribute has a modifier, it must be in an attribute block at the top of a source file.

If a source file contains an attribute block at the top of the file that specifies attributes for the assembly or module that will contain the source file, each attribute in the attribute block must be prefixed by either the **Assembly** or **Module** modifier and a colon.

```
Attributes ::= < AttributeList >
AttributeList ::=
   Attribute |
   AttributeList , Attribute
Attribute ::=
   [ AttributeModifier : ] TypeName [ ( [ AttributeArguments ] ) ]
AttributeModifier ::= Assembly | Module
```

5.1 Attribute Classes | 5.2.1 Attribute Names | 5.2.2 Attribute Arguments | 5. Attributes |
Attributes (Visual Basic Language Concepts)

5.2.1 Attribute Names

The name of an attribute specifies an attribute class. By convention, attribute classes are named with the suffix `Attribute`. Uses of an attribute may either include or omit this suffix. Consequently the name of an attribute class that corresponds to an attribute identifier is either the identifier itself or the concatenation of the qualified identifier and `Attribute`. When the compiler resolves an attribute name, it appends `Attribute` to the name and tries the lookup. If that lookup fails, the compiler tries the lookup without the suffix. For example, uses of an attribute class `SimpleAttribute` may omit the `Attribute` suffix, thus shortening the name to `Simple`:

```
<Simple()> _
Class Class1
End Class

<Simple()> _
Interface Interface1
End Interface
```

The example above is semantically equivalent to the following:

```
<SimpleAttribute()> _
Class Class1
End Class

<SimpleAttribute()> _
Interface Interface1
End Interface
```

In general, attributes named with the suffix `Attribute` are preferred. The following example shows two attribute classes named `X` and `XAttribute`.

```
<AttributeUsage(AttributeTargets.All)> _
Public Class X
    Inherits System.Attribute
End Class

<AttributeUsage(AttributeTargets.All)> _
Public Class XAttribute
    Inherits System.Attribute
End Class

' Refers to XAttribute.
<X()> _
Class Class1
End Class

' Refers to XAttribute.
<XAttribute()> _
Class Class2
End Class
```

Both the attribute block `<X>` and the attribute block `<XAttribute>` refer to the attribute class named `XAttribute`. It is not possible to use `X` as an attribute until you remove the declaration for class `XAttribute`.

See Also

5.1 Attribute Classes | 5.2 Attribute Blocks | 5.2.2 Attribute Arguments | 5. Attributes | Attributes (Visual Basic Language Concepts)

5.2.2 Attribute Arguments

Arguments to an attribute may take two forms: positional arguments and instance variable/property initializers. Any positional arguments to the attribute must precede the instance variable/property initializers. A positional argument consists of a constant expression or a **GetType** expression. An instance variable/property initializer consists of an identifier, which can match keywords, followed by a colon and equal sign, and terminated by a constant expression or a **GetType** expression.

Given an attribute with attribute class `T`, positional argument list `P`, and instance variable/property initializer list `N`, these steps determine whether the arguments are valid:

1. Follow the compile-time processing steps for compiling an expression of the form `New T(P)`. This either results in a compile-time error or determines a constructor on `T` that is most applicable to the argument list.
2. If the constructor determined in step 1 has parameters that are not attribute types or is inaccessible at the declaration site, a compile-time error occurs.
3. For each instance variable/property initializer `Arg` in `N`:
   a. Let `Name` be the identifier of the instance variable/property initializer `Arg`.
   b. `Name` must identify a non-**Shared**, writeable, **Public** instance variable or parameterless property on `T` whose type is an attribute type. If `T` has no such instance variable or property, a compile-time error occurs.

For example:

```
Imports System

<AttributeUsage(AttributeTargets.All)> _
Public Class GeneralAttribute
    Inherits Attribute

    Public Sub New(ByVal x As Integer)
    End Sub

    Public Sub New(Byval x As Double)
    End Sub

    Public y As Type

    Public Property z As Integer
        Get
        End Get

        Set
        End Set
    End Property
End Class

' Calls the first constructor.
<General(10, z := 30, y := GetType(Integer))> _
Class Foo
End Class

' Calls the second constructor.
<General(10.5, z := 10)> _
Class Bar
End Class
```

```
AttributeArguments ::=
   AttributePositionalArgumentList |
   AttributePositionalArgumentList , VariablePropertyInitializerList |
   VariablePropertyInitializerList
AttributePositionalArgumentList ::=
   ConstantExpression |
   AttributePositionalArgumentList , ConstantExpression
VariablePropertyInitializerList ::=
   VariablePropertyInitializer |
```

```
    VariablePropertyInitializerList , VariablePropertyInitializer
VariablePropertyInitializer ::=
    IdentifierOrKeyword : = ConstantExpression
```

5.1 Attribute Classes | 5.2 Attribute Blocks | 5.2.1 Attribute Names | 5. Attributes | Attributes (Visual Basic Language Concepts)

6. Source Files and Namespaces

A Visual Basic .NET program consists of one or more source files. When a program is compiled, all of the source files are processed together; thus, source files can depend on each other, possibly in a circular fashion, without any forward-declaration requirement. The textual order of declarations in the program text is generally of no significance.

A source file consists of an optional set of option statements, import statements, and attributes, which are followed by a namespace body. The attributes, which must each have either the **Assembly** or **Module** modifier, apply to the .NET assembly or module produced by the compilation. The body of the source file functions as an implicit namespace declaration for the global namespace, meaning that all declarations at the top level of a source file are placed in the global namespace. For example:

```
File A.vb:
    Class A
    End Class

File B.vb:
    Class B
    End Class
```

The two source files contribute to the global namespace, in this case declaring two classes with the fully qualified names `A` and `B`. Because the two source files contribute to the same declaration space, it would have been an error if each contained a declaration of a member with the same name.

The compilation environment may override the namespace declarations into which a source file is implicitly placed.

```
Start ::=
   [ OptionStatement+ ]
   [ ImportsStatement+ ]
   [ Attributes ]
   [ NamespaceMemberDeclaration+ ]
```

See Also

6.2 Compilation Options | 6.3 Imports Statement | 6.4 Namespaces | Namespace Statement (Visual Basic Language Reference) | Namespaces (Visual Basic Language Concepts)

6.1 Program Startup and Termination

Program startup occurs when the execution environment executes a designated method, which is referred to as the program's *entry point*. This entry point method, which must always be named `Main`, must be shared and must have one of the following signatures:

```
Sub Main()
Sub Main(ByVal Args() As String)
Function Main() As Integer
Function Main(ByVal Args() As String) As Integer
```

The accessibility of the entry point method is irrelevant. If a program contains more than one suitable entry point, the compilation environment must designate one as the entry point. Otherwise, a compile-time error occurs. The compilation environment may also create an entry point method if one does not exist.

When a program begins, if the entry point has a parameter, the argument supplied by the execution environment contains the command-line arguments to the program represented as strings. If the entry point has a return type of `Integer`, then the value returned from the function is returned to the execution environment as the result of the program.

In all other respects, entry point methods behave in the same manner as other methods. When execution leaves the invocation of the entry point method made by the execution environment, the program terminates.

See Also

6. Source Files and Namespaces | 6.2 Compilation Options | 6.3 Imports Statement | 6.4 Namespaces

6.2 Compilation Options

A source file can specify compilation options in the source code using *option statements*. An **Option** statement applies only to the source file in which it appears, and only one of each type of **Option** statement may appear in a source file. For example:

```
Option Strict On
Option Compare Text
Option Strict Off    ' Not allowed, Option Strict is already specified.
Option Compare Text  ' Not allowed, Option Compare is already specified.
```

There are three compilation options: strict type semantics, explicit declaration semantics, and comparison semantics. If a source file does not include a particular **Option** statement, then the compilation environment determines which particular set of semantics will be used. There is also a fourth compilation option, integer overflow 0checks, which can only be specified through the compilation environment.

```
OptionStatement ::=
   OptionExplicitStatement |
   OptionStrictStatement |
   OptionCompareStatement
```

See Also

6.2.1 Option Explicit Statement | 6.2.2 Option Strict Statement | 6.2.3 Option Compare Statement | 6.3 Imports Statement | 6.4 Namespaces | Visual Basic Compiler Options (Visual Basic Language Reference)

6.2.1 Option Explicit Statement

The **Option Explicit** statement determines whether local variables may be implicitly declared. The keywords **On** or **Off** may follow the statement; if neither is specified, the default is **On**. If no statement is specified in a file, the compilation environment determines which will be used.

> **Note** **Explicit** and **Off** are not reserved words.

```
Option Explicit Off

Module Test
    Sub Main()
        x = 5 ' Valid because Option Explicit is off.
    End Sub
End Module
```

In this example, the local variable `x` is implicitly declared by assigning to it. The type of `x` is `Object`.

```
OptionExplicitStatement ::= Option Explicit [ OnOff ] LineTerminator
OnOff ::= On | Off
```

See Also

6.2.2 Option Strict Statement | 6.2.3 Option Compare Statement | 6.2.4 Integer Overflow Checks | 6.2 Compilation Options | 10.1.1 Local Variables and Parameters | Option Explicit Statement (Visual Basic Language Reference)

6.2.2 Option Strict Statement

The **Option Strict** statement determines whether conversions and operations on **Object** are governed by strict or permissive type semantics and whether types are implicitly typed as **Object** if no **As** clause is specified. The statement may be followed by the keywords **On** or **Off**; if neither is specified, the default is **On**. If no statement is specified in a file, the compilation environment determines which will be used.

> **Note** **Strict** and **Off** are not reserved words.

```
Option Strict On

Module Test
    Sub Main()
        Dim x ' Error, no type specified.
        Dim o As Object
        Dim b As Byte = o ' Error, narrowing conversion.

        o.Foo() ' Error, late binding disallowed.
        o = o + 1 ' Error, addition is not defined on Object.
    End Sub
End Module
```

Under strict semantics, the following are disallowed:

- Narrowing conversions without an explicit cast operator.
- Late binding.
- Operations on type **Object** other than **=**, **<>**, **TypeOf**...**Is**, and **Is**.
- Omitting the **As** clause in a declaration.

```
OptionStrictStatement ::= Option Strict [ OnOff ] LineTerminator
```

See Also

6.2.1 Option Explicit Statement | 6.2.3 Option Compare Statement | 6.2.4 Integer Overflow Checks | 6.2 Compilation Options | Option Strict Statement (Visual Basic Language Reference)

6.2.3 Option Compare Statement

The **Option Compare** statement determines the semantics of string comparisons. String comparisons are carried out either using binary comparisons (in which the binary Unicode value of each character is compared) or text comparisons (in which the lexical meaning of each character is compared using the current culture). If no statement is specified in a file, the compilation environment controls which type of comparison will be used.

> **Note** **Compare**, **Binary**, and **Text** are not reserved words.

```
Option Compare Text

Imports System

Module M
    Sub Main()
        Console.WriteLine("a" = "A")    ' Prints True.
    End Sub
End Module
```

In this case, the string comparison is done using a text comparison that ignores case differences. If **Option Compare Binary** had been specified, then this would have printed **False**.

```
OptionCompareStatement ::= Option Compare CompareOption LineTerminator
CompareOption ::= Binary | Text
```

See Also

6.2.1 Option Explicit Statement | 6.2.2 Option Strict Statement | 6.2.4 Integer Overflow Checks | 6.2 Compilation Options | 11.15 Like Operator | Option Compare Statement (Visual Basic Language Reference)

6.2.4 Integer Overflow Checks

Integer operations can either be checked or not checked for overflow conditions at run time. If overflow conditions are checked and an integer operation overflows, a **System.OverflowException** exception is thrown. If overflow conditions are not checked, integer operation overflows do not throw an exception. The compilation environment determines whether this option is on or off.

See Also

6.2.1 Option Explicit Statement | 6.2.2 Option Strict Statement | 6.2.3 Option Compare Statement | 6.2 Compilation Options | 11.12 Operator Expressions | Visual Basic Compiler Options (Visual Basic Language Reference)

6.3 Imports Statement

Imports statements import the names of entities into a source file, allowing the names to be referenced without qualification.

Within member declarations in a source file that contains an **Imports** statement, the types contained in the given namespace can be referenced directly, as seen in the following example:

```
Imports N1.N2

Namespace N1.N2
    Class A
    End Class
End Namespace

Namespace N3
    Class B
        Inherits A
    End Class
End Namespace
```

Here, within the source file, the type members of namespace `N1.N2` are directly available, and thus class `N3.B` derives from class `N1.N2.A`.

Imports statements must appear after any **Option** statements but before any type declarations. The compilation environment may also define implicit **Imports** statements.

Imports statements make names available in a source file, but do not declare anything in the global namespace's declaration space. The scope of the names imported by an **Imports** statement extends over the namespace member declarations contained in the source file. The scope of an **Imports** statement specifically does not include other **Imports** statements, nor does it include other source files. **Imports** statements may not refer to one another.

In this example, the last **Imports** statement is in error because it is not affected by the first import alias.

```
Imports R1 = N1 ' OK.
Imports R2 = N1.N2 ' OK.
Imports R3 = R1.N2 ' Error: Can't refer to R1.

Namespace N1.N2
End Namespace
```

> **Note** The namespace or type names that appear in **Imports** statements are always treated as if they are fully qualified. That is, the leftmost identifier in a namespace or type name always resolves in the global namespace and the rest of the resolution proceeds according to normal name resolution rules. This is the only place in the language that applies such a rule; the rule ensures that a name cannot be completely hidden from qualification. Without the rule, if a name in the global namespace were hidden in a particular source file, it would be impossible to specify any names from that namespace in a qualified way.

In this example, the **Imports** statement always refers to the global `System` namespace, and not the class in the source file.

```
Imports System   ' Imports the namespace, not the class.

Class System
End Class
```

Imports Statement (Visual Basic Language Reference) | References and the Imports Statement (Visual Basic Language Concepts)

6.3.1 Import Aliases

An *import alias* defines an alias for a namespace or type.

```
Imports A = N1.N2.A

Namespace N1.N2
    Class A
    End Class
End Namespace

Namespace N3
    Class B
        Inherits A
    End Class
End Namespace
```

Here, within the source file, `A` is an alias for `N1.N2.A`, and thus class `N3.B` derives from class `N1.N2.A`. The same effect can be obtained by creating an alias `R` for `N1.N2` and then referencing `R.A`:

```
Imports R = N1.N2

Namespace N3
    Class B
        Inherits R.A
    End Class
End Namespace
```

The identifier of an import alias must be unique within the declaration space of the global namespace (not just the global namespace declaration in the source file in which the import alias is defined), even though it does not declare a name in the global namespace's declaration space.

```
Imports A = N3.A

Class A
End Class

Namespace N3
    Class A
    End Class
End Namespace
```

Here, the global namespace already contains a member `A`, so it is an error for an import alias to use that identifier. It is likewise an error for two or more import aliases in the same source file to declare aliases by the same name.

An import alias can create an alias for any namespace or type. Accessing a namespace or type through an alias yields exactly the same result as accessing the namespace or type through its declared name.

```
Imports R1 = N1
Imports R2 = N1.N2

Namespace N1.N2
    Class A
    End Class
End Namespace

Namespace N3
    Class B
        Private a As N1.N2.A
        Private b As R1.N2.A
        Private c As R2.A
    End Class
End Namespace
```

Here, the names `N1.N2.A`, `R1.N2.A`, and `R2.A` are equivalent, and all refer to the class whose fully qualified name is `N1.N2.A`.

Declarations in the source file may shadow the import alias name.

```
Imports R = N1.N2

Namespace N1.N2
    Class A
    End Class
End Namespace

Namespace N3
    Class R
    End Class

    Class B
        Inherits R.A  ' Error, R has no member A
    End Class
End Namespace
```

In the preceding example the reference to `R.A` in the declaration of `B` causes an error because `R` refers to `N3.R`, not `N1.N2`.

An import alias makes an alias available within a particular source file, but it does not contribute any new members to the underlying declaration space. In other words, an import alias is not transitive, but rather affects only the source file in which it occurs.

File1.vb:

```
Imports R = N1.N2

Namespace N1.N2
    Class A
    End Class
End Namespace
```

File2.vb:

```
Class B
    Inherits R.A ' Error, R unknown.
End Class
```

In the above example, because the scope of the import alias that introduces `R` only extends to declarations in the source file in which it is contained, `R` is unknown in the second source file.

```
ImportsAliasClause ::= Identifier = NamespaceOrTypeName
```

See Also

6.3.2 Namespace Imports | 6.3 Imports Statement | Imports Statement (Visual Basic Language Reference) | References and the Imports Statement (Visual Basic Language Concepts)

6.3.2 Namespace Imports

A *namespace import* imports all of the members of a namespace or type, allowing the identifier of each member of the namespace or type to be used without qualification. In the case of types, a namespace import only allows access to the shared members of the type without requiring qualification of the class name. In particular, it allows the members of enumerated types to be used without qualification. For example:

```
Imports Colors

Enum Colors
    Red
    Green
    Blue
End Enum

Module M1
    Sub Main()
        Dim c As Colors = Red
    End Sub
End Module
```

Unlike an import alias, a namespace import has no restrictions on the names it imports and may import namespaces and types whose identifiers are already declared within the global namespace. The names imported by a regular import are shadowed by import aliases and declarations in the source file.

In the following example, `A` refers to `N3.A` rather than `N1.N2.A` within member declarations in the `N3` namespace.

```
Imports N1.N2

Namespace N1.N2
    Class A
    End Class
End Namespace

Namespace N3
    Class A
    End Class

    Class B
        Inherits A
    End Class
End Namespace
```

When more than one imported namespace contains members by the same name (and that name is not otherwise shadowed by an import alias or declaration), a reference to that name is ambiguous and causes a compile-time error.

```
Imports N1
Imports N2

Namespace N1
    Class A
    End Class
End Namespace

Namespace N2
    Class A
    End Class
End Namespace

Namespace N3
    Class B
        Inherits A ' Error, A is ambiguous.
    End Class
End Namespace
```

In the above example, both `N1` and `N2` contain a member `A`. Because `N3` imports both, referencing `A` in `N3` causes a compile-time error. In this situation, the conflict can be resolved either through qualification of references to `A`, or by introducing an import alias that picks a particular `A`, as in the following example:

```
Imports N1
Imports N2
Imports A = N1.A

Namespace N3
    Class B
        Inherits A ' A means N1.A.
    End Class
End Namespace
```

Only namespaces, classes, structures, enumerated types, and standard modules may be imported.

```
ImportsNamespaceClause ::= NamespaceOrTypeName
```

See Also

6.3.1 Import Aliases | 6.3 Imports Statement | Imports Statement (Visual Basic Language Reference) | References and the Imports Statement (Visual Basic Language Concepts)

6.4 Namespaces

Visual Basic .NET programs are organized using namespaces. Namespaces both internally organize a program as well as organize the way program elements are exposed to other programs.

Unlike other entities, namespaces are open-ended, and may be declared multiple times within the same program and across many programs, with each declaration contributing members to the same namespace. In the following example, the two namespace declarations contribute to the same declaration space, declaring two classes with the fully qualified names `N1.N2.A` and `N1.N2.B`.

```
Namespace N1.N2
    Class A
    End Class
End Namespace

Namespace N1.N2
    Class B
    End Class
End Namespace
```

Because the two declarations contribute to the same declaration space, it would be an error if each contained a declaration of a member with the same name.

There is a global namespace that has no name and whose nested namespaces and types can always be accessed without qualification. The scope of a namespace member declared in the global namespace is the entire program text. Otherwise, the scope of a type or namespace declared in a namespace whose fully qualified name is **N** is the program text of each namespace whose corresponding namespace's fully qualified name begins with **N** or is **N** itself.

In this example, the class `B` can see the class `A` because `B`'s namespace `N1.N2.N3` is conceptually nested within the namespace `N1.N2`.

```
Namespace N1.N2
    Class A
    End Class
End Namespace

Namespace N1.N2.N3
    Class B
        Inherits A
    End Class
End Namespace
```

See Also

6.4.1 Namespace Declarations | 6.4.2 Namespace Members | 6.2 Compilation Options | 6.3 Imports Statement | Namespace Statement (Visual Basic Language Reference) | Namespaces (Visual Basic Language Concepts)

6.4.1 Namespace Declarations

A namespace declaration consists of the keyword **Namespace** followed by a qualified identifier and optional namespace member declarations. If the namespace name is qualified, the namespace declaration is treated as if it is lexically nested within namespace declarations corresponding to each name in the qualified name. For example, the following two namespaces are semantically equivalent:

```
Namespace N1.N2
    Class A
    End Class

    Class B
    End Class
End Namespace

Namespace N1
    Namespace N2
        Class A
        End Class

        Class B
        End Class
    End Namespace
End Namespace
```

When dealing with the members of a namespace, it is not important where a particular member is declared. If two programs define an entity with the same name in the same namespace, attempting to resolve the name in the namespace causes an ambiguity error.

Namespaces are by definition **Public**, so a namespace declaration cannot include any access modifiers.

```
NamespaceDeclaration ::=
   Namespace QualifiedIdentifier LineTerminator
   [ NamespaceMemberDeclaration+ ]
   End Namespace LineTerminator
```

See Also

6.4.2 Namespace Members

Namespace members can only be namespace declarations and type declarations. Type declarations may have **Public** or **Friend** access. The default access for types is **Friend** access.

```
NamespaceMemberDeclaration ::=
   NamespaceDeclaration |
   TypeDeclaration
TypeDeclaration ::=
   ModuleDeclaration |
   NonModuleDeclaration
NonModuleDeclaration ::=
   EnumDeclaration |
   StructureDeclaration |
   InterfaceDeclaration |
   ClassDeclaration |
   DelegateDeclaration
```

7. Types

The two fundamental categories of types in Visual Basic .NET are *value types* and *reference types*. Primitive types (except strings), enumerations, and structures are value types. Classes, strings, standard modules, interfaces, arrays, and delegates are reference types.

With two exceptions, all types are either value types or reference types.

- The root type **Object**, which is an alias for **System.Object**, is a **MustInherit** type that is neither a reference type nor a value type. Thus, a variable of type **Object** can either contain a value type or a reference type.
- The type **System.Void**, which represents a void type in the .NET Framework, can be referenced only in **GetType** expressions.

Every type has a *default value*, which is the value that is assigned to variables of that type upon initialization.

```
TypeName ::=
   NamespaceOrTypeName |
   BuiltInTypeName |
   ArrayTypeName
BuiltInTypeName ::= Object | PrimitiveTypeName
```

7.1 Value Types and Reference Types

Although value types and reference types can be similar in terms of declaration syntax and usage, their semantics are distinct.

Reference types are stored on the run-time heap; they may only be accessed through a reference to that storage. Because reference types are always accessed through references, their lifetime is managed by the .NET Framework. Outstanding references to a particular instance are tracked and the instance is destroyed only when no more references remain. A variable of reference type contains a reference to a value of that type, a value of a more derived type, or a null reference. A *null reference* is a reference that refers to nothing; it is not possible to do anything with a null reference except assign it. Assignment to a variable of a reference type creates a copy of the reference rather than a copy of the referenced value. For a variable of a reference type, the default value is a null reference.

Value types are stored directly on the stack, either within an array or within another type; their storage can only be accessed directly. Because value types are stored directly within variables, their lifetime is determined by the lifetime of the variable that contains them. When the location containing a value type instance is destroyed, the value type instance is also destroyed. Value types are always accessed directly; it is not possible to create a reference to a value type. Prohibiting such a reference makes it impossible to refer to a value class instance that has been destroyed. Because value types are always **NotInheritable**, a variable of a value type always contains a value of that type. Because of this, the value of a value type cannot be a null reference, nor can it reference an object of a more derived type. Assignment to a variable of a value type creates a copy of the value being assigned. For a variable of a value type, the default value is the result of initializing each variable member of the type to its default value.

The following example shows the difference between reference types and value types:

```
Imports System

Class Class1
    Public Value As Integer = 0
End Class

Module Test
    Sub Main()
        Dim val1 As Integer = 0
        Dim val2 As Integer = val1
        val2 = 123
        Dim ref1 As Class1 = New Class1()
        Dim ref2 As Class1 = ref1
        ref2.Value = 123
        Console.WriteLine("Values: " & val1 & ", " & val2)
        Console.WriteLine("Refs: " & ref1.Value & ", " & ref2.Value)
    End Sub
End Module
```

The output of the program is:

```
Values: 0, 123
Refs: 123, 123
```

The assignment to the local variable `val2` does not impact the local variable `val1` because both local variables are of a value type (the type **Integer**) and each local variable of a value type has its own storage. In contrast, the assignment `ref2.Value = 123;` affects the object that both `ref1` and `ref2` reference.

Value types and reference types are unified under the type **Object**, which is the root type of all types. Because **Object** is neither a reference nor a value type, it can contain values of either kind and has semantics consistent with the kind of type contained within it at run time.

The following example shows how **Object** can be used with both value types and reference types:

```
Imports System

Class Class1
    Public Value As Integer = 0
End Class

Structure Struct1
```

```
    Public Value As Integer
End Structure

Module Test
    Sub Main()
        Dim val1 As Object = New Struct1()
        Dim val2 As Object = val1

        val2.Value = 123

        Dim ref1 As Object = New Class1()
        Dim ref2 As Object = ref1

        ref2.Value = 123

        Console.WriteLine("Values: " & val1.Value & ", " & val2.Value)
        Console.WriteLine("Refs: " & ref1.Value & ", " & ref2.Value)
    End Sub
End Module
```

The output of the program is:

```
Values: 0, 123
Refs: 123, 123
```

The assignment to the field of the local variable `val2` does not impact the field of the local variable `val1` because both local variables are of a value type (the type **Integer**) and each local variable of a value type has its own storage. In contrast, the assignment `ref2.Value = 123` affects the object that both `ref1` and `ref2` references.

7.2 Interface Implementation

Structure and class declarations may declare that they implement a set of interface types through one or more **Implements** clauses. All the types specified in the **Implements** clause must be interfaces, and the type must implement all members of the interfaces. For example:

```
Interface ICloneable
    Function Clone() As Object
End Interface

Interface IComparable
    Function CompareTo(ByVal other As Object) As Integer
End Interface

Structure ListEntry
    Implements ICloneable, IComparable

    Public Function Clone() As Object Implements ICloneable.Clone
    End Function

    Public Function CompareTo(ByVal other As Object) As Integer _
        Implements IComparable.CompareTo
    End Function
End Structure
```

A type that implements an interface also implicitly implements all of the interface's base interfaces. This is true even if the type does not explicitly list all base interfaces in the **Implements** clause. In this example, the `TextBox` structure implements both `IControl` and `ITextBox`.

```
Interface IControl
    Sub Paint()
End Interface

Interface ITextBox
    Inherits IControl
    Sub SetText(ByVal Text As String)
End Interface

Structure TextBox
    Implements ITextBox

    Public Sub Paint() Implements ITextBox.Paint
    End Sub

    Public Sub SetText(ByVal Text As String) Implements ITextBox.SetText
    End Sub
End Structure
```

Declaring that a type implements an interface in and of itself does not declare anything in the declaration space of the type. Thus, it is valid to implement two interfaces with a method by the same name.

```
TypeImplementsClause ::= Implements Implements LineTerminator
Implements ::=
   TypeName |
   Implements , TypeName
```

7.3 Primitive Types

The *primitive types* are identified through keywords, which are aliases for predefined types in the **System** namespace. A primitive type is completely indistinguishable from the type it aliases: writing the reserved word **Byte** is exactly the same as writing **System.Byte**.

Because a primitive type aliases a regular type, every primitive type has members. For example, **Integer** has the members declared in **System.Int32**. Literals can be treated as instances of their corresponding types.

The primitive types differ from other structure types in that they permit certain additional operations:

- Primitive types permit values to be created by writing literals. For example, `123I` is a literal of type **Integer**.
- It is possible to declare constants of the primitive types.
- When the operands of an expression are all primitive type constants, it is possible for the compiler to evaluate the expression at compile time. Such an expression is known as a constant expression.

Visual Basic .NET defines the following primitive types:

- The integral value types **Byte** (1-byte unsigned integer), **Short** (2-byte signed integer), **Integer** (4-byte signed integer), and **Long** (8-byte signed integer). These types map to **System.Byte**, **System.Int16**, **System.Int32**, and **System.Int64**, respectively. The default value of an integral type is equivalent to the literal `0`.
- The floating-point value types **Single** (4-byte floating point) and **Double** (8-byte floating point). These types map to **System.Single** and **System.Double**, respectively. The default value of a floating-point type is equivalent to the literal `0`.
- The **Decimal** type (16-byte decimal value), which maps to **System.Decimal**. The default value of decimal is equivalent to the literal `0D`.
- The **Boolean** value type, which represents a truth value, typically the result of a relational or logical operation. The literal is of type **System.Boolean**. The default value of the **Boolean** type is equivalent to the literal **False**.
- The **Date** value type, which represents a date and/or a time and maps to **System.DateTime**. The default value of the **Date** type is equivalent to the literal `# 01/01/0001 12:00:00AM #`.
- The **Char** value type, which represents a single Unicode character and maps to **System.Char**. The default value of the **Char** type is equivalent to the constant expression `ChrW(0)`.
- The **String** reference type, which represents a sequence of Unicode characters and maps to **System.String**. The default value of the **String** type is a null reference.

```
PrimitiveTypeName ::= NumericTypeName | Boolean | Date | Char | String
NumericTypeName ::= IntegralTypeName | FloatingPointTypeName | Decimal
IntegralTypeName ::= Byte | Short | Integer | Long
FloatingPointTypeName ::= Single | Double
```

7.4 Enumerations

Enumerations are value types that inherit from **System.Enum** and symbolically represent a set of values of one of the primitive integral types. For an enumeration type `E`, the default value is the value produced by the expression `CType(0, E)`.

The underlying type of an enumeration must be an integral type that can represent all the enumerator values defined in the enumeration. If an underlying type is specified, it must be **Byte**, **Short**, **Integer**, or **Long**. If no underlying type is explicitly specified, the default is **Integer**.

The following example declares an enumeration with an underlying type of **Long**:

```
Enum Color As Long
    Red
    Green
    Blue
End Enum
```

A developer might choose to use an underlying type of **Long**, as in the example, to enable the use of values that are in the range of **Long**, but not in the range of **Integer**, or to preserve this option for the future.

```
EnumDeclaration ::=
   [ Attributes ] [ EnumModifier+ ] Enum Identifier
      [ As IntegralTypeName ] LineTerminator
   EnumMemberDeclaration+
   End Enum LineTerminator
EnumModifier ::= AccessModifier | Shadows
```

See Also

7.4.1 Enumeration Members

The members of an enumeration are the enumerated values declared in the enumeration and the members inherited from class **System.Enum**.

The scope of an enumeration member is the enumeration declaration body. This means that outside of an enumeration declaration, an enumeration member must always be qualified (unless the type is specifically imported into a namespace through a namespace import).

Declaration order for enumeration member declarations is significant when constant expression values are omitted. Enumeration members implicitly have **Public** access only; no access modifiers are allowed on enumeration member declarations.

```
EnumMemberDeclaration ::=
   [ Attributes ] Identifier [ = ConstantExpression ] LineTerminator
```

See Also

7.4.2 Enumeration Values | 7.4 Enumerations | Enum Statement (Visual Basic Language Reference) | Enumerations Overview(Visual Basic Language Concepts)

7.4.2 Enumeration Values

The enumerated values in an enumeration member list are declared as constants typed as the underlying enumeration type, and they can appear wherever constants are required. An enumeration member definition with **=** gives the associated member the value indicated by the constant expression. The constant expression must evaluate to an integral type that is implicitly convertible to the underlying type and must be within the range of values that can be represented by the underlying type. The following example is in error because the constant values `1.5`, `2.3`, and `3.3` are not implicitly convertible to the underlying integral type **Long** with strict semantics.

```
Option Strict On

Enum Color As Long
    Red = 1.5
    Green = 2.3
    Blue = 3.3
End Enum
```

Multiple enumeration members may share the same associated value, as shown below:

```
Enum Color
    Red
    Green
    Blue
    Max = Blue
End Enum
```

The example shows an enumeration that has two enumeration members — `Blue` and `Max` — that have the same associated value.

If the first enumerator value definition in the enumeration has no initializer, the value of the corresponding constant is `0`. An enumeration value definition without an initializer gives the enumerator the value obtained by increasing the value of the previous enumeration value by `1`. This increased value must be within the range of values that can be represented by the underlying type.

```
Imports System

Enum Color
    Red
    Green = 10
    Blue
End Enum

Module Test
    Sub Main()
        Console.WriteLine(StringFromColor(Color.Red))
        Console.WriteLine(StringFromColor(Color.Green))
        Console.WriteLine(StringFromColor(Color.Blue))
    End Sub

    Function StringFromColor(ByVal c As Color) As String
        Select Case c
            Case Color.Red
                Return String.Format("Red = " & CInt(c))

            Case Color.Green
                Return String.Format("Green = " & CInt(c))

            Case Color.Blue
                Return String.Format("Blue = " & CInt(c))

            Case Else
                Return "Invalid color"
        End Select
    End Function
End Class
```

The example above prints the enumeration values and their associated values. The output is:

```
Red = 0
Blue = 11
Green = 10
```

The reasons for the values are as follows:

- The enumeration value `Red` is automatically assigned the value `0` (since it has no initializer and is the first enumeration value member).
- The enumeration value `Green` is explicitly given the value `10`.
- The enumeration value `Blue` is automatically assigned the value one greater than the enumeration value that textually precedes it.

The constant expression may not directly or indirectly use the value of its own associated enumeration value (that is, circularity in the constant expression is not allowed). The following example is invalid because the declarations of `A` and `B` are circular.

```
Enum Circular
    A = B
    B
End Enum
```

`A` depends on `B` explicitly, and `B` depends on `A` implicitly.

7.5 Classes

A *class* is a data structure that may contain data members (constants, variables, and events), function members (methods, properties, indexers, operators, and constructors), and nested types. Classes are reference types. The following example shows a class that contains each kind of member:

```
Imports System

Class AClass

    Public Sub New()
        Console.WriteLine("Constructor")
    End Sub

    Public Sub New(ByVal value As Integer)
        MyVariable = value
        Console.WriteLine("Constructor")
    End Sub

    Public Const MyConst As Integer = 12
    Public MyVariable As Integer = 34

    Public Sub MyMethod()
        Console.WriteLine("MyClass.MyMethod")
    End Sub

    Public Property MyProperty() As Integer
        Get
            Return MyVariable
        End Get

        Set (ByVal value As Integer)
            MyVariable = value
        End Set
    End Property

    Default Public Property Item(ByVal index As Integer) As Integer
        Get
            Return 0
        End Get

        Set (ByVal value As Integer)
            Console.WriteLine("Item(" & index & ") = " & value)
        End Set
    End Property

    Public Event MyEvent()

    Friend Class MyNestedClass
    End Class
End Class
```

The following example shows uses of these members:

```
Imports System

Module Test

    ' Event usage.
    Dim WithEvents aInstance As AClass

    Sub Main()
        ' Constructor usage.
        Dim a As AClass = New AClass()
        Dim b As AClass = New AClass(123)
```

```
        ' Constant usage.
        Console.WriteLine("MyConst = " & AClass.MyConst)

        ' Variable usage.
        a.MyVariable += 1
        Console.WriteLine("a.MyVariable = " & a.MyVariable)

        ' Method usage.
        a.MyMethod()

        ' Property usage.
        a.MyProperty += 1
        Console.WriteLine("a.MyProperty = " & a.MyProperty)
        a(1) = 1

        ' Event usage.
        aInstance = a
    End Sub

    Sub MyHandler() Handles aInstance.MyEvent
        Console.WriteLine("Test.MyHandler")
    End Sub
End Module
```

There are two class-specific modifiers, **MustInherit** and **NotInheritable**. It is invalid to specify them both.

```
ClassDeclaration ::=
   [ Attributes ] [ ClassModifier+ ] Class Identifier LineTerminator
   [ ClassBase ]
   [ TypeImplementsClause+ ]
   [ ClassMemberDeclaration+ ]
   End Class LineTerminator
ClassModifier ::= AccessModifier | Shadows | MustInherit | NotInheritable
```

7.5.1 Class Base Specification

A class declaration may include a base type specification that defines the direct base type of the class. If a class declaration has no explicit base type, the direct base type is implicitly **Object**. For example:

```
Class Base
End Class

Class Derived
    Inherits Base
End Class
```

Classes may only derive from **Object** and classes. It is invalid for a class to derive from **System.ValueType**, **System.Enum**, **System.Array**, or **System.Delegate**.

Every class has exactly one direct base class, and circularity in derivation is prohibited. It is not possible to derive from a **NotInheritable** class, and the accessibility domain of the base class must be the same as or a superset of the accessibility domain of the class itself.

```
ClassBase ::= Inherits TypeName LineTerminator
```

See Also

7.2 Interface Implementation | 7.5.2 Class Members | 7.5 Classes | Inherits Statement (Visual Basic Language Reference)

7.5.2 Class Members

The members of a class consist of the members introduced by its class member declarations and the members inherited from its direct base class.

A class member declaration may have **Public**, **Protected**, **Friend**, **Protected Friend**, or **Private** access. When a class member declaration does not include an access modifier, the declaration defaults to **Public** access, unless it is a variable declaration; in that case it defaults to **Private** access.

The scope of a class member is the class body in which the declaration occurs. If the member has **Friend** access, its scope extends to the class body of any derived class in the same program, and if the member has **Public**, **Protected**, or **Protected Friend** access, its scope extends to the class body of any derived class in any program.

```
ClassMemberDeclaration ::=
   NonModuleDeclaration |
   EventMemberDeclaration |
   VariableMemberDeclaration |
   ConstantMemberDeclaration |
   MethodMemberDeclaration |
   PropertyMemberDeclaration |
   ConstructorMemberDeclaration
```

7.6 Structures

Structures are value types that inherit from **System.ValueType**. Structures are similar to classes in that they represent data structures that can contain data members and function members. Unlike classes, however, structures do not require heap allocation.

In the case of classes, it is possible for two variables to reference the same object, and thus possible for operations on one variable to affect the object referenced by the other variable. With structures, the variables each have their own copy of the data, so it is not possible for operations on one to affect the other, as the following example illustrates:

```
Structure Point
    Public x, y As Integer

    Public Sub New(ByVal x As Integer, ByVal y As Integer)
        Me.x = x
        Me.y = y
    End Sub
End Structure
```

Given the above declaration the following code fragment outputs the value `10`:

```
Point a = new Point(10, 10)
Point b = a

a.x = 100
System.Console.WriteLine(b.x)
```

The assignment of `a` to `b` creates a copy of the value, and `b` is thus unaffected by the assignment to `a.x`. Had `Point` instead been declared as a class, the output would be `100` because `a` and `b` would reference the same object.

```
StructureDeclaration ::=
   [ Attributes ] [ StructureModifier+ ] Structure Identifier
      LineTerminator
   [ TypeImplementsClause+ ]
   [ StructMemberDeclaration+ ]
   End Structure LineTerminator
StructureModifier ::= AccessModifier | Shadows
```

7.6.1 Structure Members

The members of a structure are the members introduced by its structure member declarations and the members inherited from **System.ValueType**. Structures must contain at least one instance variable.

Every structure implicitly has a **Public** parameterless instance constructor that produces the default value of the structure. As a result, it is not possible for a structure type declaration to declare a parameterless instance constructor. A structure type is, however, permitted to declare *parameterized* instance constructors, as in the following example:

```
Structure Point
    Private x, y As Integer

    Public Sub New(ByVal x As Integer, ByVal y As Integer)
        Me.x = x
        Me.y = y
    End Sub
End Structure
```

Given the above declaration, the following statements both create a `Point` with `x` and `y` initialized to zero.

```
Dim p1 As Point = New Point()
Dim p2 As Point = New Point(0, 0)
```

Normally, a structure member declaration may only have **Public**, **Friend**, or **Private** access, but when overriding members inherited from **Object**, **Protected** and **Protected Friend** access may also be used. When a structure member declaration does not include an access modifier, the declaration defaults to **Public** access. The scope of a member declared by a structure is the structure body in which the declaration occurs.

```
StructMemberDeclaration ::=
   NonModuleDeclaration |
   VariableMemberDeclaration |
   ConstantMemberDeclaration |
   EventMemberDeclaration |
   MethodMemberDeclaration |
   PropertyMemberDeclaration |
   ConstructorMemberDeclaration
```

7.2 Interface Implementation | 7.6 Structures | Structure Statement (Visual Basic Language Reference) | Structures: Your Own Data Types (Visual Basic Language Concepts)

7.7 Standard Modules

A *standard module* is a type whose members are implicitly **Shared** and scoped to the declaration space of the standard module's containing namespace, rather than just to the standard module declaration itself. Standard modules may never be instantiated. It is an error to declare a variable of a standard module type.

A member of a standard module has two fully qualified names, one without the standard module name and one with the standard module name. More than one standard module in a namespace may define a member with a particular name; unqualified references to the name outside of either module are ambiguous. For example:

```
Namespace N1
    Module M1
        Sub S1()
        End Sub

        Sub S2()
        End Sub
    End Module

    Module M2
        Sub S2()
        End Sub
    End Module

    Module M3
        Sub Main()
            S1() ' Valid: Calls N1.M1.S1.
            N1.S1() ' Valid: Calls N1.M1.S1.
            S2() ' Not valid: ambiguous.
            N1.S2() ' Not valid: ambiguous.
            N1.M2.S2() ' Valid: Calls N1.M2.S2.
        End Sub
    End Module
End Namespace
```

A module may only be declared in a namespace and may not be nested in another type. Standard modules may not implement interfaces, they implicitly derive from **Object**, and they have only **Shared** constructors.

```
ModuleDeclaration ::=
   [ Attributes ] [ AccessModifier+ ] Module Identifier LineTerminator
   [ ModuleMemberDeclaration+ ]
   End Module LineTerminator
```

7.7.1 Standard Module Members

The members of a standard module are the members introduced by its member declarations and the members inherited from **Object**. Standard modules may have any type of member except instance constructors. All standard module type members are implicitly **Shared**.

Normally, a standard module member declaration may only have **Public**, **Friend**, or **Private** access, but when overriding members inherited from **Object**, the **Protected** and **Protected Friend** access modifiers may be specified. When a standard module member declaration does not include an access modifier, the declaration defaults to **Public** access, unless it is a variable, which defaults to **Private** access.

As previously noted, the scope of a standard module member is the declaration containing the standard module declaration. Members inherited from **Object** are not included in this special scoping; those members have no scope and must always be qualified with the name of the module. If the member has **Friend** access, its scope extends only to namespace members declared in the same program.

```
ModuleMemberDeclaration ::=
   NonModuleDeclaration |
   VariableMemberDeclaration |
   ConstantMemberDeclaration |
   EventMemberDeclaration |
   MethodMemberDeclaration |
   PropertyMemberDeclaration |
   ConstructorMemberDeclaration
```

7.7 Standard Modules | Module Statement (Visual Basic Language Reference) |
Shared Members (Visual Basic Language Concepts)

7.8 Interfaces

Interfaces are reference types that other types implement to guarantee that they support certain methods. An interface is never directly created and has no actual representation — other types must be converted to an interface type. An interface defines a contract. A class or structure that implements an interface must adhere to its contract.

The following example shows an interface that contains a default property `Item`, an event `E`, a method `F`, and a property `P`:

```
Interface IExample
    Default Property Item(ByVal index As Integer) As String
    Event E()
    Sub F(ByVal value As Integer)
    Property P() As String
End Interface
```

Interfaces may employ multiple inheritance. In the following example, the interface `IComboBox` inherits from both `ITextBox` and `IListBox`:

```
Interface IControl
    Sub Paint()
End Interface

Interface ITextBox
    Inherits IControl
    Sub SetText(ByVal Text As String)
End Interface

Interface IListBox
    Inherits IControl
    Sub SetItems(ByVal items() As String)
End Interface

Interface IComboBox
    Inherits ITextBox, IListBox
End Interface
```

Classes and structures can implement multiple interfaces. In the following example, the class `EditBox` derives from the class `Control` and implements both `IControl` and `IDataBound`:

```
Interface IDataBound
    Sub Bind(ByVal b As Binder)
End Interface

Public Class EditBox
    Inherits Control
    Implements IControl, IDataBound

    Public Sub Paint() Implements IControl.Paint
        ' ...
    End Sub

    Public Sub Bind(ByVal b As Binder) Implements IDataBound.Bind
    End Sub
End Class
```

```
InterfaceDeclaration ::=
   [ Attributes ] [ InterfaceModifier+ ] Interface Identifier
      LineTerminator
   [ InterfaceBase+ ]
   [ InterfaceMemberDeclaration+ ]
   End Interface LineTerminator
InterfaceModifier ::= AccessModifier | Shadows
```

7.8.1 Interface Inheritance

The base interfaces of an interface are the explicit base interfaces and their base interfaces. In other words, the set of base interfaces is the complete transitive closure of the explicit base interfaces, their explicit base interfaces, and so on. If an interface declaration has no explicit interface base, then there is no base interface for the type. In the following example, the base interfaces of `IComboBox` are `IControl`, `ITextBox`, and `IListBox`.

```
Interface IControl
    Sub Paint()
End Interface

Interface ITextBox
    Inherits IControl
    Sub SetText(ByVal Text As String)
End Interface

Interface IListBox
    Inherits IControl
    Sub SetItems(ByVal items() As String)
End Interface

Interface IComboBox
    Inherits ITextBox, IListBox
End Interface
```

An interface inherits all members of its base interfaces. In other words, the `IComboBox` interface above inherits members `SetText` and `SetItems` as well as `Paint`.

A class or structure that implements an interface also implicitly implements all of the interface's base interfaces.

If an interface appears more than once in the transitive closure of the base interfaces, it only contributes its members to the derived interface once. A type implementing the derived interface only has to implement the methods of the multiply defined base interface once. In the following example, `Paint` only needs to be implemented once, even though the class implements `IComboBox` and `IControl`.

```
Class ComboBox
    Implements IControl, IComboBox

    Sub SetText(ByVal Text As String) Implements IComboBox.SetText
    End Sub

    Sub SetItems(ByVal items() As String) Implements IComboBox.SetItems
    End Sub

    Sub Print() Implements IComboBox.Paint
    End Sub
End Class
```

An **Inherits** clause has no effect on other **Inherits** clauses. In the following example, `IDerived` must qualify the name of `INested` with `IBase`.

```
Interface IBase
    Interface INested
        Sub Nested()
    End Interface

    Sub Base()
End Interface

Interface IDerived
    Inherits IBase, INested   ' Error: Must specify IBase.INested.
End Interface
```

The accessibility domain of a base interface must be the same as or a superset of the accessibility domain of the interface itself.

```
InterfaceBase ::= Inherits InterfaceBases LineTerminator
InterfaceBases ::=
   TypeName |
   InterfaceBases , TypeName
```

See Also

7.8.2 Interface Members | 7.8 Interfaces | Inherits Statement (Visual Basic Language Reference)

7.8.2 Interface Members

The members of an interface consist of the members introduced by its member declarations and the members inherited from its base interfaces.

Only nested types, methods, properties, and events may be members of an interface. Methods and properties may not have a body. Interface members are implicitly **Public** and may not specify an access modifier. Interface members have no scope, and they must always be qualified.

```
InterfaceMemberDeclaration ::=
   NonModuleDeclaration |
   EventMemberDeclaration |
   MethodMemberDeclaration |
   PropertyMemberDeclaration
```

7.8.1 Interface Inheritance | 7.8 Interfaces | Interfaces in Visual Basic .NET (Visual Basic Language Concepts)

7.9 Arrays

An *array* is a reference type that contains variables accessed through *indices* corresponding in a one-to-one fashion with the order of the variables in the array. The variables contained in an array, also called the *elements* of the array, must all be of the same type, and this type is called the *element type* of the array. The elements of an array come into existence when an array instance is created, and cease to exist when the array instance is destroyed. Each element of an array is initialized to the default value of its type. The type **System.Array** is the base type of all array types and may not be instantiated. Every array type inherits the members declared by the **System.Array** type and is convertible to it (and **Object**).

An array has a *rank* that determines the number of indices associated with each array element. The rank of an array determines the number of *dimensions* of the array. For example, an array with a rank of one is called a single-dimensional array, and an array with a rank greater than one is called a multidimensional array.

The following example creates a single-dimensional array of integer values, initializes the array elements, and then prints each of them out:

```
Imports System

Module Test
    Sub Main()
        Dim arr(5) As Integer
        Dim i As Integer

        For i = 0 To arr.Length - 1
            arr(i) = i * i
        Next i

        For i = 0 To arr.Length - 1
            Console.WriteLine("arr(" & i & ") = " & arr(i))
        Next i
    End Sub
End Module
```

The program outputs the following:

```
arr(0) = 0
arr(1) = 1
arr(2) = 4
arr(3) = 9
arr(4) = 16
arr(5) = 25
```

Each dimension of an array has an associated length. Dimension lengths are not part of the type of the array, but rather are established when an instance of the array type is created at run time. The length of a dimension determines the valid range of indices for that dimension: for a dimension of length `N`, indices can range from zero to `N - 1`. If a dimension is of length zero, there are no valid indices for that dimension. The total number of elements in an array is the product of the lengths of each dimension in the array. If any of the dimensions of an array has a length of zero, the array is said to be empty. The element type of an array can be any type.

Array types are specified by adding a modifier to an existing type name. The modifier consists of a left parenthesis, a set of zero or more commas, and a right parenthesis. The type modified is the element type of the array, and the number of dimensions is the number of commas plus one. If more than one modifier is specified, then the element type of the array is an array. The modifiers are read left to right, with the leftmost modifier being the outermost array. In the example

```
Module Test
    Dim arr As Integer(,)(,,)()
End Module
```

the element type of `arr` is a two-dimensional array of three-dimensional arrays of one-dimensional arrays of **Integer**.

A variable may also be declared to be of an array type by putting an array type modifier or an array initialization modifier on the variable name. In that case, the array element type is the type given in the declaration, and the array dimensions are determined by the variable name modifier. For clarity, it is not valid to have an array type modifier on both a variable name and a type name

in the same declaration.

The following example shows a variety of local variable declarations that use array types with **Integer** as the element type:

```
Module Test
    Sub Main()
        Dim a1() As Integer    ' Declares 1-dimensional array of integers.
        Dim a2(,) As Integer   ' Declares 2-dimensional array of integers.
        Dim a3(,,) As Integer  ' Declares 3-dimensional array of integers.

        Dim a4 As Integer()    ' Declares 1-dimensional array of integers.
        Dim a5 As Integer(,)   ' Declares 2-dimensional array of integers.
        Dim a6 As Integer(,,)  ' Declares 3-dimensional array of integers.

        ' Declare 1-dimensional array of 2-dimensional arrays of integers
        Dim a7()(,) As Integer
        ' Declare 2-dimensional array of 1-dimensional arrays of integers.
        Dim a8(,)() As Integer

        Dim a9() As Integer() ' Not allowed.
    End Sub
End Module
```

An array type name modifier extends to all sets of parentheses that follow it. This means that in the situations where a set of arguments enclosed in parenthesis is allowed after a type name, it is not possible to specify the arguments for an array type name. For example:

```
Module Test
    Sub Main()
        ' This calls the Integer constructor.
        Dim x As New Integer(3)

        ' This declares a variable of Integer().
        Dim y As Integer()

        ' This gives an error.
        ' Array sizes can not be specified in a type name.
        Dim z As Integer()(3)
    End Sub
End Module
```

In the last case, `(3)` is interpreted as part of the type name rather than as a set of constructor arguments.

```
ArrayTypeName ::= TypeName ArrayTypeModifiers
ArrayTypeModifiers ::= ArrayTypeModifier+
ArrayTypeModifier ::= ( [ RankList ] )
RankList ::=
   , |
   RankList ,
ArrayNameModifier ::=
   ArrayTypeModifiers |
   ArraySizeInitializationModifier
```

7.1 Value Types and Reference Types | 7.3 Primitive Types | 7.4 Enumerations | 7.6 Structures | 7.5 Classes | 7.7 Standard Modules | 7.8 Interfaces | 7.10 Delegates | Arrays Summary (Visual Basic Language Reference) | Arrays (Visual Basic Language Concepts)

7.10 Delegates

A *delegate* is a reference type that refers to a **Shared** method of a type or to an instance method of an object. The closest equivalent of a delegate in other languages is a function pointer, but whereas a function pointer can only reference **Shared** functions, a delegate can reference both **Shared** and instance methods. In the latter case, the delegate stores not only a reference to the method's entry point, but also a reference to the object instance with which to invoke the method.

The method declaration may not have attributes, modifiers, a **Handles** clause, an **Implements** clause, a method body, or an **End** construct. The parameter list of the method declaration may not contain **Optional** or **ParamArray** parameters. The accessibility domain of the return type and parameter types must be the same as or a superset of the accessibility domain of the delegate itself.

The members of a delegate are the members inherited from class **System.Delegate**. A delegate also contains a set of constructors and methods defined by the system. As these are specified and implemented by the .NET Framework, they are not listed here.

There are three steps in defining and using delegates: declaration, instantiation, and invocation.

Delegates are declared using delegate declaration syntax. The following example declares a delegate named `SimpleDelegate` that takes no arguments:

```
Delegate Sub SimpleDelegate()
```

The next example creates a `SimpleDelegate` instance and then immediately calls it:

```
Imports System

Module Test
    Sub F()
        System.Console.WriteLine("Test.F")
    End Sub

    Sub Main()
        Dim d As SimpleDelegate = AddressOf F
        d()
    End Sub
End Module
```

There is not much point in instantiating a delegate for a method and then immediately calling via the delegate, as it would be simpler to call the method directly. Delegates show their usefulness when their anonymity is used. The next example shows a `MultiCall` method that repeatedly calls a `SimpleDelegate` instance:

```
Sub MultiCall(ByVal d As SimpleDelegate, ByVal count As Integer)
    Dim i As Integer

    For i = 0 To count - 1
        d()
    Next i
End Sub
```

It is unimportant to the `MultiCall` method what the target method for the `SimpleDelegate` is, what accessibility this method has, or whether the method is **Shared** or nonshared. All that matters is that the signature of the target method is compatible with `SimpleDelegate`.

```
DelegateDeclaration ::=
   [ Attributes ] [ DelegateModifier+ ] Delegate MethodDeclaration
DelegateModifier ::= AccessModifier | Shadows
```

8. Conversions

Conversion is the process of changing a value from one type to another. Conversions may either be widening or narrowing. A *widening conversion* is a conversion from one type to another type that is guaranteed to be able to contain it. Widening conversions never fail. A *narrowing conversion* may fall into one of two categories. One category is a conversion from one type to another type that is not guaranteed to be able to contain it. The other category is a conversion between types that are sufficiently unrelated as to have no obvious conversion. Narrowing conversions, which entail loss of information, may fail.

See Also

8.1 Implicit and Explicit Conversions | 8.5 Array Covariance | 8.8 Widening Conversions | 8.9 Narrowing Conversions | Conversion Summary (Visual Basic Language Reference) | Type Conversions (Visual Basic Language Concepts)

8.1 Implicit and Explicit Conversions

Conversions can be either *implicit* or *explicit*. Implicit conversions occur without any special syntax. The following is an example of implicit conversion of an **Integer** value to a **Long** value:

```
Module Test
    Sub Main()
        Dim intValue As Integer = 123
        Dim longValue As Long = intValue

        Console.WriteLine(intValue & " = " & longValue)
    End Sub
End Module
```

Explicit conversions, on the other hand, require cast operators. Attempting to do an explicit conversion on a value without a cast operator causes a compile-time error. The following example uses an explicit conversion to convert a **Long** value to an **Integer** value.

```
Module Test
    Sub Main()
        Dim longValue As Long = 134
        Dim intValue As Integer = CInt(longValue)

        Console.WriteLine(longValue & " = " & intValue)
    End Sub
End Module
```

The set of implicit conversions depends on the compilation environment and the **Option Strict** statement. If strict semantics are being used, only widening conversions may occur implicitly. If permissive semantics are being used, all widening and narrowing conversions may occur implicitly.

See Also

8.5 Array Covariance | 8.8 Widening Conversions | 8.9 Narrowing Conversions | 8. Conversions |
Conversion Summary (Visual Basic Language Reference) | Implicit and Explicit Conversions (Visual Basic Language Concepts)

8.2 Boolean Conversions

Although **Boolean** is not a numeric type, it does have conversions to and from the numeric types as if it were an enumerated type. The literal **True** converts to the literal `255` for **Byte** and to the expression `-1` for **Short**, **Integer**, **Long**, **Decimal**, **Single**, and **Double**. The literal **False** converts to the literal `0`. A zero numeric value converts to the literal **False**. All other numeric values convert to the literal **True**.

See Also

8.5 Array Covariance | 8.8 Widening Conversions | 8.9 Narrowing Conversions | 8. Conversions |
Conversion Summary (Visual Basic Language Reference) | Implicit and Explicit Conversions (Visual Basic Language Concepts)

8.3 Numeric Conversions

Numeric conversions are conversions between the types **Byte**, **Short**, **Integer**, **Long**, **Decimal**, **Single** and **Double**, and enumerated types. Enumerated types are treated as if they were their underlying types for the purpose of conversions. When converting from a numeric type to an enumerated type, the numeric type is never required to conform to the set of values defined in the enumerated type.

Numeric conversions are processed at run-time as follows:

- For a conversion from a numeric type to a wider numeric type, the value is simply converted to the wider type. Conversions from **Integer**, **Long**, or **Decimal** to **Single** or **Double** are rounded to the nearest **Single** or **Double** value. While this conversion may cause a loss of precision, it will never cause a loss of magnitude.
- For a conversion from an integral type to a smaller integral type, or from **Single**, **Double**, or **Decimal** to an integral type, the result depends on whether integer overflow checking is on:

  If integer overflow is being checked:

  - If the source is an integral type, the conversion succeeds if the source argument is within the range of the destination type. The conversion throws a **System.OverflowException** exception if the source argument is outside the range of the destination type.
  - If the source is **Single**, **Double**, or **Decimal**, the source value is rounded up or down to the nearest integral value, and this integral value becomes the result of the conversion. If the source value is equally close to two integral values, the value is rounded to the value that has an even number in the least significant digit position. If the resulting integral value is outside the range of the destination type, a **System.OverflowException** exception is thrown.

  If integer overflow is not being checked:

  - If the source is an integral type, the conversion always succeeds and simply consists of discarding the most significant bits of the source value.
  - If the source is **Single**, **Double**, or **Decimal**, the conversion always succeeds and simply consists of rounding the source value towards the nearest integral value. If the source value is equally close to two integral values, the value is always rounded to the value that has an even number in the least significant digit position.
  - For a conversion from **Double** to **Single**, the **Double** value is rounded to the nearest **Single** value. If the **Double** value is too small to represent as a **Single**, the result becomes positive zero or negative zero. If the **Double** value is too large to represent as a **Single**, the result becomes positive infinity or negative infinity. If the **Double** value is NaN, the result is also NaN.
- For a conversion from **Single** or **Double** to **Decimal**, the source value is converted to **Decimal** representation and rounded to the nearest number after the 28th decimal place if required. If the source value is too small to represent as a **Decimal**, the result becomes zero. If the source value is NaN, infinity, or too large to represent as a **Decimal**, a **System.OverflowException** exception is thrown.
- For a conversion from **Double** to **Single**, the **Double** value is rounded to the nearest **Single** value. If the **Double** value is too small to represent as a **Single**, the result becomes positive zero or negative zero. If the **Double** value is too large to represent as a **Single**, the result becomes positive infinity or negative infinity. If the **Double** value is NaN, the result is also NaN.

Conversion Summary (Visual Basic Language Reference) | Implicit and Explicit Conversions (Visual Basic Language Concepts)

8.4 Reference Conversions

A value typed as a reference type may always be converted to a base type. Conversions from a base type to a derived type only succeed at run time if the value being converted is a null reference or a reference type that is either the derived type itself or a more derived type.

Within the .NET Framework, it is possible to know at compile time whether a class type implements a particular interface type. Consequently, a class type can always be cast to an interface type that it implements. Similarly, conversions from an interface type to a class type that implements it only succeed at run time if the value being converted is a null reference or a reference type that is either the class type itself or a type derived from the class type.

However, classes that represent COM classes may have interface implementations that are not known until run time. Consequently, a class type may also be converted to an interface type that it does not implement, an interface type may be converted to a class type that does not implement it, and an interface type may be converted to another interface type with which it has no inheritance relationship. In all these cases, a check is performed at run time by the .NET Framework to determine if the class type involved implements the required interface types.

If a reference conversion fails at run time, a **System.InvalidCastException** exception is thrown.

Conversion Summary (Visual Basic Language Reference) | Implicit and Explicit Conversions (Visual Basic Language Concepts)

8.5 Array Covariance

For any two reference types `A` and `B`, if `A` is a derived type of `B`, a conversion exists from an array of type `A` to a compatible array of type `B`. A *compatible array* is an array of the same rank and type. This relationship is known as *array covariance*. Array covariance in particular means that an element of an array whose element type is `B` may actually be an element of an array whose element type is `A`, provided that both `A` and `B` are reference types and that `B` is a base type of `A`. In the following example, the second invocation of `F` causes a **System.ArrayTypeMismatchException** exception to be thrown because the actual element type of `b` is **String**, not **Object**:

```
Module Test
    Sub F(ByRef x As Object)
    End Sub

    Sub Main()
        Dim a(10) As Object
        Dim b() As Object = New String(10) {}
        F(a(0)) ' OK.
        F(b(1)) ' Not allowed: System.ArrayTypeMismatchException.
   End Sub
End Module
```

Because of array covariance, assignments to elements of reference type arrays include a run-time check that ensures that the value being assigned to the array element is actually of a permitted type.

```
Module Test
    Sub Fill(array() As Object, index As Integer, count As Integer, _
            value As Object)
        Dim i As Integer

        For i = index To (index + count) - 1
            array(i) = value
        Next i
    End Sub

    Sub Main()
        Dim strings(100) As String

        Fill(strings, 0, 101, "Undefined")
        Fill(strings, 0, 10, Nothing)
        Fill(strings, 91, 10, 0)
    End Sub
End Module
```

In this example, the assignment to `array(i)` in method `Fill` implicitly includes a run-time check that ensures that the object referenced by the variable `value` is either **Nothing** or an instance of a type that is compatible with the actual element type of array `array`. In method `Main`, the first two invocations of method `Fill` succeed, but the third invocation causes a **System.ArrayTypeMismatchException** exception to be thrown upon executing the first assignment to `array(i)`. The exception occurs because an **Integer** cannot be stored in a **String** array.

Array covariance specifically does not extend to arrays of value types.

Conversion Summary (Visual Basic Language Reference) | Array Conversions (Visual Basic Language Concepts)

8.6 Value Type Conversions

Although interfaces are reference types, value types may be converted to and from them. When converting a value type to an interface, the value type is copied to the .NET Framework heap and a reference is returned. This reference is then converted to the interface type.

When converting an interface type to a value type, the value must be a null reference or an instance of the value type. Otherwise a **System.InvalidCastException** exception is thrown. The conversion copies the value on the .NET Framework heap to the stack and converts it to the value type. A null reference is treated as if it were the literal **Nothing**.

See Also

8.5 Array Covariance | 8.8 Widening Conversions | 8.9 Narrowing Conversions | 8. Conversions |
Conversion Summary (Visual Basic Language Reference) | Array Conversions (Visual Basic Language Concepts)

8.7 String Conversions

Converting **Char** into **String** results in a string whose first character is the character value. Converting **String** into **Char** results in a character whose value is the first character of the string. Converting an array of **Char** into **String** results in a string whose characters are the elements of the array. Converting **String** into an array of **Char** results in an array of characters whose elements are the characters of the string.

The exact conversions between **String** and **Boolean**, **Byte**, **Short**, **Integer**, **Long**, **Decimal**, **Single**, **Double**, **Date**, and vice versa, are beyond the scope of this specification and are implementation dependent with the exception of one detail. String conversions always consider the current culture of the run-time environment. As such, they must be performed at run time.

Conversion Summary (Visual Basic Language Reference) | Array Conversions (Visual Basic Language Concepts)

8.8 Widening Conversions

Widening conversions never overflow but may entail a loss of precision. The following conversions are widening conversions:

- Conversions from any derived type to one of its base types.
- Numeric type conversions in the following direction: **Byte**, **Short**, **Integer**, **Long**, **Decimal**, **Single**, **Double**. Conversions from **Integer** to **Single**, **Long** to **Single** or **Double**, or **Decimal** to **Single** or **Double** may cause a loss of precision, but will never cause a loss of magnitude. The other widening numeric conversions never lose any information.
- Conversions from the literal **Nothing** to any type.
- Conversions from the literal `0` to any enumerated type.
- Conversions from any enumerated type to its underlying type, or to any type that its underlying type has a widening conversion to.
- Conversions from any reference or value type to an interface type that the value or reference type implements.
- Conversions from an array type `S` with an element type `SE` to a covariant-array type `T` with an element type `TE`, provided all of the following are true:
  - `S` and `T` differ only in element type.
  - Both `SE` and `TE` are reference types.
  - A widening reference conversion exists from `SE` to `TE`.
- Conversions from **Char** to **String**.
- Conversions from **Char()** to **String**.
- Conversions from a constant expression of type **Long**, **Integer**, **Short**, or **Byte** to a narrower type, provided the value of the constant expression is within the range of the destination type.

See Also

8.5 Array Covariance | 8.9 Narrowing Conversions | 8. Conversions | Conversion Summary (Visual Basic Language Reference) | Widening and Narrowing Conversions (Visual Basic Language Concepts)

8.9 Narrowing Conversions

Narrowing conversions are conversions that cannot be proved to always succeed, conversions that are known to possibly lose information, and conversions across domains of types sufficiently different to merit narrowing notation. The following conversions are classified as narrowing conversions:

- Conversions from any type to a more derived type.
- Numeric type conversions in the following direction: **Double**, **Single**, **Decimal**, **Long**, **Integer**, **Short**, **Byte**.
- Conversions from **Boolean** to any numeric type.
- Conversions from any numeric type to **Boolean**.
- Conversions from any numeric type to any enumerated type.
- Conversions from any enumerated type to any type its underlying type has a narrowing conversion to.
- Conversions from any enumerated type to any other enumerated type.
- Conversions from any class type to any interface type, provided the class type does not implement the interface type.
- Conversions from any interface type to any class type.
- Conversions from any interface type to any value type that implements the interface type.
- Conversions from any interface type to any other interface type, provided there is no inheritance relationship between the two types.
- Conversions from an array type `S` with an element type `SE`, to a covariant-array type `T` with an element type `TE`, provided that all of the following are true:
    - `S` and `T` differ only in element type.
    - Both `SE` and `TE` are reference types.
    - A narrowing reference conversion exists from `SE` to `TE`.
- Conversions from **String** to **Char**.
- Conversions from **String** to **Char()**.
- Conversions from **String** to **Boolean** and from **Boolean** to **String**.
- Conversions between **String** and **Byte**, **Short**, **Integer**, **Long**, **Decimal**, **Single**, or **Double**.
- Conversions from **String** to **Date** and from **Date** to **String**.

9. Type Members

Type members define storage locations and executable code. They can be methods, constructors, events, constants, variables, and properties.

See Also

9.2 Methods | 9.3 Constructors | 9.4 Events | 9.5 Constants | 9.6 Instance and Shared Variables | 9.7 Properties | Objects, Properties, Methods, and Events (Visual Basic Language Concepts)

9.1 Interface Method Implementation

Methods, events, and properties can implement interface members. To implement an interface member, a member declaration specifies the **Implements** keyword and lists one or more interface members. Methods and properties that implement interface members are implicitly **NotOverridable** unless declared to be **MustOverride**, **Overridable**, or overriding another member. It is an error for a member implementing an interface member to be **Shared**. A member's accessibility has no effect on its ability to implement interface members.

For an interface implementation to be valid, the implements list of the containing type must name an interface that contains a compatible member. A compatible member is one whose signature matches the signature of the implementing member. If an event declared using a delegate type is implementing an interface event, then a compatible event is one whose underlying delegate type is the same type. Otherwise, the event uses the delegate type from the interface event it is implementing. If such an event implements multiple interface events, all the interface events must have the same underlying delegate type. For example:

```
Interface ClickEvents
    Event LeftClick(ByVal x As Integer, ByVal y As Integer)
    Event RightClick(ByVal x As Integer, ByVal y As Integer)
End Interface

Class Button
    Implements ClickEvents

    ' OK. Signatures match, delegate type = ClickEvents.LeftClickHandler.
    Event LeftClick(ByVal x As Integer, ByVal y As Integer) _
        Implements ClickEvents.LeftClick

    ' OK. Signatures match, delegate type = ClickEvents.RightClickHandler.
    Event RightClick(ByVal x As Integer, ByVal y As Integer) _
        Implements ClickEvents.RightClick
End Class

Class Label
    Implements ClickEvents

    ' Error. Signatures match, but can't be both delegate types.
    Event Click(ByVal x As Integer, ByVal y As Integer) _
        Implements ClickEvents.LeftClick, ClickEvents.RightClick
End Class
```

An interface member in the implements list is specified using a type name, a period, and an identifier. The type name must be an interface in the implements list or a base interface of an interface in the implements list, and the identifier must be a member of the specified interface. A single member can implement more than one matching interface member.

```
Interface ILeft
    Sub F()
End Interface

Interface IRight
    Sub F()
End Interface

Class Test
    Implements ILeft, IRight

    Sub F() Implements ILeft.F, IRight.F
    End Sub
End Class
```

If the interface member being implemented is unavailable in all explicitly implemented interfaces because of multiple interface inheritance, the implementing member must explicitly reference a base interface on which the member is available. For example, if `I1` and `I2` contain a member `M`, and `I3` inherits from `I1` and `I2`, a type implementing `I3` will implement `I1.M` and `I2.M`. If an interface shadows multiply inherited members, an implementing type will have to implement the inherited members and the member(s) shadowing them.

```
Interface ILeft
    Sub F()
End Interface

Interface IRight
    Sub F()
End Interface

Interface ILeftRight
    Inherits ILeft, IRight

    Shadows Sub F()
End Interface

Class Test
    Implements ILeftRight

    Sub LeftF() Implements ILeft.F
    End Sub

    Sub RightF() Implements IRight.F
    End Sub

    Sub LeftRightF() Implements ILeftRight.F
    End Sub
End Sub
```

```
ImplementsClause ::= [ Implements ImplementsList ]
ImplementsList ::=
   InterfaceMemberSpecifier |
   ImplementsList , InterfaceMemberSpecifier
InterfaceMemberSpecifier ::= TypeName . Identifier
```

9.2 Methods

Methods contain the executable statements of a program. Methods, which have an optional list of parameters and an optional return value, are either shared or nonshared. Shared methods are accessed through the class or instances of the class. Nonshared methods, also called instance methods, are accessed through instances of the class. The following example shows a class `Stack` that has several shared methods (`Clone` and `Flip`), and several instance methods (`Push`, `Pop`, and `ToString`):

```
Imports System

Public Class Stack
    Public Shared Function Clone(ByVal s As Stack) As Stack
    End Function

    Public Shared Function Flip(ByVal s As Stack) As Stack
    End Function

    Public Function Pop() As Object
    End Function

    Public Sub Push(ByVal o As Object)
    End Sub

    Public Overrides Function ToString() As String
    End Function
End Class

Module Test
    Sub Main()
        Dim s As Stack = New Stack()
        Dim i As Integer

        While i < 10
            s.Push(i)
        End While

        Dim flipped As Stack = Stack.Flip(s)
        Dim cloned As Stack = Stack.Clone(s)

        Console.WriteLine("Original stack: " & s.ToString())
        Console.WriteLine("Flipped stack: " & flipped.ToString())
        Console.WriteLine("Cloned stack: " & cloned.ToString())
    End Sub
End Module
```

Methods can be overloaded, which means that multiple methods may have the same name so long as they have unique signatures. The signature of a method consists of the name of the method and the number and types of its parameters. The signature of a method specifically does not include the return type or parameter modifiers. The following example shows a class with a number of `F` methods:

```
Imports System

Module Test
    Sub F()
        Console.WriteLine("F()")
    End Sub

    Sub F(ByVal o As Object)
        Console.WriteLine("F(Object)")
    End Sub

    Sub F(ByVal value As Integer)
        Console.WriteLine("F(Integer)")
    End Sub

    Sub F(ByVal a As Integer, ByVal b As Integer)
```

```
        Console.WriteLine("F(Integer, Integer)")
    End Sub

    Sub F(ByVal values() As Integer)
        Console.WriteLine("F(Integer())")
    End Sub

    Sub Main()
        F()
        F(1)
        F(CType(1, Object))
        F(1, 2)
        F(New Integer() { 1, 2, 3 })
    End Sub
End Module
```

The output of the program is:

```
F()
F(Integer)
F(Object)
F(Integer, Integer)
F(Integer())
```

```
MethodMemberDeclaration ::= MethodDeclaration | ExternalMethodDeclaration
```

9.2.1 Regular Method Declarations

There are two types of methods: *subroutines*, which do not return values, and *functions*, which do. The body and **End** construct of a method may only be omitted if the method is defined in an interface or has the **MustOverride** modifier. If no return type is specified on a function and strict semantics are being used, a compile-time error occurs; otherwise the type is implicitly **Object** or the type of the method's type character. The accessibility domain of the return type and parameter types of a method must be the same as or a superset of the accessibility domain of the method itself.

```
MethodDeclaration ::= SubDeclaration | FunctionDeclaration
SubDeclaration ::=
   [ Attributes ] [ ProcedureModifier+ ] Sub Identifier
      [ ( [ ParameterList ] ) ] [ HandlesOrImplements ] LineTerminator
   [ Block ]
   [ End Sub LineTerminator ]
FunctionDeclaration ::=
   [ Attributes ] [ ProcedureModifier+ ] Function Identifier
      [ ( [ ParameterList ] ) ] [ As [ Attributes ] TypeName ]
      [ HandlesOrImplements ] LineTerminator
   [ Block ]
   [ End Function LineTerminator ]
ProcedureModifier ::=
   AccessModifier |
   Shadows |
   Shared |
   Overridable |
   NotOverridable |
   MustOverride |
   Overrides |
   Overloads
HandlesOrImplements ::= HandlesClause | ImplementsClause
```

9.2.2 External Method Declarations

An external method declaration introduces a new method whose implementation is provided external to the program. Because an external method declaration provides no actual implementation, it has no method body or **End** construct. External methods are implicitly shared and may not handle events or implement interface members. If no return type is specified on a function and strict semantics are being used, a compile-time error occurs. Otherwise the type is implicitly **Object** or the type of the method's type character. The accessibility domain of the return type and parameter types of an external method must be the same as or a superset of the accessibility domain of the external method itself.

The library clause of an external method declaration specifies the name of the external file that implements the method. The optional alias clause is a string that specifies the numeric ordinal (prefixed by a `@` character) or name of the method in the external file. A single-character set modifier may also be specified, which governs the character set used to marshal strings during a call to the external method. The **Unicode** modifier marshals all strings to Unicode values, the **Ansi** modifier marshals all strings to ANSI values, and the **Auto** modifier marshals the strings according to .NET Framework rules based on the name of the method, or the alias name if specified. If no modifier is specified, the default is **Ansi**.

If **Ansi** or **Unicode** is specified, then the method name is looked up in the external file with no modification. If **Auto** is specified, then method name lookup depends on the platform. If the platform is considered to be ANSI (for example, Windows 95, Windows 98, Windows ME), then the method name is looked up with no modification. If the lookup fails, an `A` is appended and the lookup tried again. If the platform is considered to be Unicode (for example, Windows NT, Windows 2000, Windows XP), then a `W` is appended and the name is looked up. If the lookup fails, the lookup is tried again without the `W`. For example:

```
Module Test
    ' All platforms bind to "ExternSub".
    Declare Ansi Sub ExternSub Lib "ExternDLL" ()

    ' All platforms bind to "ExternSub".
    Declare Unicode Sub ExternSub Lib "ExternDLL" ()

    ' ANSI platforms: bind to "ExternSub" then "ExternSubA".
    ' Unicode platforms: bind to "ExternSubW" then "ExternSub".
    Declare Auto Sub ExternSub Lib "ExternDLL" ()
End Module
```

Data types being passed to external methods are marshaled according to the .NET Framework data marshalling conventions with one exception. String variables that are passed by value (that is, `ByVal x As String`) are marshaled to the OLE Automation BSTR type, and changes made to the BSTR in the external method are reflected back in the string argument. This is because the type **String** in external methods is mutable, and this special marshalling mimics that behavior. String parameters that are passed by reference (i.e. `ByRef x As String`) are marshaled as a pointer to the OLE Automation BSTR type. It is possible to override these special behaviors by specifying the **System.Runtime.InteropServices.MarshalAsAttribute** attribute on the parameter.

The example demonstrates use of external methods:

```
Class Path
    Declare Function CreateDirectory Lib "kernel32" ( _
        ByVal Name As String, ByVal sa As SecurityAttributes) As Boolean
    Declare Function RemoveDirectory Lib "kernel32" ( _
        ByVal Name As String) As Boolean
    Declare Function GetCurrentDirectory Lib "kernel32" ( _
        ByVal BufSize As Integer, ByVal Buf As String) As Integer
    Declare Function SetCurrentDirectory Lib "kernel32" ( _
        ByVal Name As String) As Boolean
End Class
```

```
ExternalMethodDeclaration ::=
   ExternalSubDeclaration |
   ExternalFunctionDeclaration
ExternalSubDeclaration ::=
   [ Attributes ] [ ExternalMethodModifier+ ] Declare
      [ CharsetModifier ] Sub Identifier LibraryClause
      [ AliasClause ] [ ( [ ParameterList ] ) ] LineTerminator
ExternalFunctionDeclaration ::=
   [ Attributes ] [ ExternalMethodModifier+ ] Declare
```

```
        [ CharsetModifier ] Function Identifier LibraryClause
        [ AliasClause ] [ ( [ ParameterList ] ) ]
        [ As [ Attributes ] TypeName ] LineTerminator
  ExternalMethodModifier ::= AccessModifier | Shadows | Overloads
  CharsetModifier ::= Ansi | Unicode | Auto
  LibraryClause ::= Lib StringLiteral
  AliasClause ::= Alias StringLiteral
```

9.2.3 Overridable Methods

The **Overridable** modifier indicates that a method is overridable. The **Overrides** modifier indicates that a method overrides a base-type overridable method that has the same signature. The **NotOverridable** modifier indicates that an overridable method cannot be further overridden. The **MustOverride** modifier indicates that a method must be overridden in derived classes.

Certain combinations of these modifiers are not valid:

- **Overridable** and **NotOverridable** are mutually exclusive and cannot be combined.
- **MustOverride** implies **Overridable** (and so cannot specify it) and cannot be combined with **NotOverridable**. **MustOverride** methods cannot override other methods, and so cannot be combined with **Overrides**.
- **NotOverridable** cannot be combined with **Overridable** or **MustOverride** and must be combined with **Overrides**.
- **Overrides** implies **Overridable** (and so cannot specify it) and cannot be combined with **MustOverride**.

There are also additional restrictions on overridable methods:

- A **MustOverride** method may not include a method body or an **End** construct, may not override another method, and may only appear in **MustInherit** classes.
- If a method specifies **Overrides** and there is no matching base method to override, a compile-time error occurs. An overriding method may not specify **Shadows**.
- A method may not override another method if the overriding method's accessibility domain is not equal to the accessibility domain of the method being overridden. The one exception is that a method overriding a **Protected Friend** method in another assembly must specify **Protected** (not **Protected Friend**).
- **Private** methods may not be **Overridable**, **NotOverridable**, or **MustOverride**, nor may they override other methods.
- Methods in **NotInheritable** classes may not be declared **Overridable** or **MustOverride**.

The following example illustrates the differences between overridable and nonoverridable methods:

```
Imports System

Class Base
    Public Sub F()
        Console.WriteLine("Base.F")
    End Sub

    Public Overridable Sub G()
        Console.WriteLine("Base.G")
    End Sub
End Class

Class Derived
    Inherits Base

    Public Shadows Sub F()
        Console.WriteLine("Derived.F")
    End Sub

    Public Overrides Sub G()
        Console.WriteLine("Derived.G")
    End Sub
End Class

Module Test
    Sub Main()
        Dim d As Derived = New Derived()
        Dim b As Base = d

        b.F()
        d.F()
        b.G()
        d.G()
    End Sub
End Module
```

In the example, class `Base` introduces a method `F` and an **Overridable** method `G`. The class `Derived` introduces a new method `F`, thus shadowing the inherited `F`, and also overrides the inherited method `G`. The example produces the following output:

```
Base.F
Derived.F
Derived.G
Derived.G
```

Notice that the statement `b.G()` invokes `Derived.G`, not `Base.G`. This is because the run-time type of the instance (which is `Derived`) rather than the compile-time type of the instance (which is `Base`) determines the actual method implementation to invoke.

See Also

9.2.1 Regular Method Declarations | 9.2.2 External Method Declarations | 9.2.3 Overridable Methods | 9.2.4 Shared Methods | 9.2.5 Method Parameters | 9.1 Interface Method Implementation | 9.2.6 Event Handling | 9.2 Methods | 4.3.3 Shadowing | Overridable (Visual Basic Language Reference) | Overrides (Visual Basic Language Reference) | Overriding Properties and Methods (Visual Basic Language Concepts)

9.2.4 Shared Methods

The **Shared** modifier indicates a method is a *shared method*. A shared method does not operate on a specific instance of a type and may be invoked directly from a type rather than through a particular instance of a type. It is valid, however, to use an instance to qualify a shared method. It is invalid to refer to **Me**, **MyClass**, or **MyBase** in a shared method. Shared methods may not be **Overridable**, **NotOverridable**, or **MustOverride**, and they may not override methods. Methods defined in standard modules and interfaces may not specify **Shared**, because they are implicitly **Shared** already.

A method declared in a structure or class without a **Shared** modifier is an *instance method*. An instance method operates on a given instance of a type. Instance methods can only be invoked through an instance of a type and may refer to the instance through the **Me** expression.

The following example illustrates the rules for accessing shared and instance members:

```
Class Test
    Private x As Integer
    Private Shared y As Integer

    Sub F()
        x = 1 ' Ok, same as Me.x = 1.
        y = 1 ' Ok, same as Test.y = 1.
    End Sub

    Shared Sub G()
        x = 1 ' Error, cannot access Me.x.
        y = 1 ' Ok, same as Test.y = 1.
    End Sub

    Shared Sub Main()
        Dim t As Test = New Test()

        t.x = 1 ' Ok.
        t.y = 1 ' Ok.
        Test.x = 1 ' Error, cannot access instance member through type.
        Test.y = 1 ' Ok.
    End Sub
End Class
```

Method `F` shows that in an instance function member, an identifier can be used to access both instance members and shared members. Method `G` shows that in a shared function member, it is an error to access an instance member through an identifier. Method `Main` shows that in a member access expression, instance members must be accessed through instances, but shared members can be accessed through types or instances.

9.2.5 Method Parameters

A *parameter* is a variable that can be used to pass information into and out of a method. Parameters of a method are declared by the method's parameter list, which consists of one or more parameters separated by commas. If no type is specified for a parameter and strict semantics are used, a compile-time error occurs. Otherwise the default type is **Object** or the type of the parameter's type character. Even under permissive semantics, if one parameter includes an **As** clause, all parameters must specify types.

Parameters are specified as value, reference, optional, or paramarray parameters by the modifiers **ByVal**, **ByRef**, **Optional**, and **ParamArray**, respectively. A parameter that does not specify **ByRef** or **ByVal** defaults to **ByVal**.

Parameter names are scoped to the entire body of the method and are always publicly accessible. A method invocation creates a copy, specific to that invocation, of the parameters, and the argument list of the invocation assigns values or variable references to the newly created parameters.

```
ParameterList ::=
   Parameter |
   ParameterList , Parameter
Parameter ::=
   [ Attributes ] ParameterModifier+ Identifier [ As TypeName ]
      [ = ConstantExpression ]
ParameterModifier ::= ByVal | ByRef | Optional | ParamArray
```

Argument Passing ByVal and ByRef (Visual Basic Language Concepts)

9.2.5.1 Value Parameters

A *value parameter* is declared with an explicit **ByVal** modifier. If the **ByVal** modifier is used, the **ByRef** modifier may not be specified. A value parameter comes into existence with the invocation of the member the parameter belongs to, and is initialized with the value of the argument given in the invocation. A value parameter ceases to exist upon return of the member.

A method is permitted to assign new values to a value parameter. Such assignments only affect the local storage location represented by the value parameter; they have no effect on the actual argument given in the method invocation.

A value parameter is used when the value of an argument is passed into a method, and modifications of the parameter do not impact the original argument. A value parameter refers to its own variable, one that is distinct from the variable of the corresponding argument. This variable is initialized by copying the value of the corresponding argument. The following example shows a method `F` that has a value parameter named `p`:

```
Imports System

Module Test
    Sub F(ByVal p As Integer)
        Console.WriteLine("p = " & p)
        p += 1
    End Sub

    Sub Main()
        Dim a As Integer = 1

        Console.WriteLine("pre: a = " & a)
        F(a)
        Console.WriteLine("post: a = " & a)
    End Sub
End Module
```

The example produces the following output, even though the value parameter `p` is modified:

```
pre: a = 1
p = 1
post: a = 1
```

9.2.5.2 Reference Parameters

A reference parameter is a parameter declared with a **ByRef** modifier. If the **ByRef** modifier is specified, the **ByVal** modifier may not be used. A reference parameter does not create a new storage location. Instead, a reference parameter represents the variable given as the argument in the method or constructor invocation. Conceptually, the value of a reference parameter is always the same as the underlying variable.

A reference parameter is used when the parameter acts as an alias for a caller-provided argument. A reference parameter does not itself define a variable, but rather refers to the variable of the corresponding argument. Modifications of a reference parameter directly and immediately impact the corresponding argument. The following example shows a method `Swap` that has two reference parameters:

```
Imports System

Module Test
    Sub Swap(ByRef a As Integer, ByRef b As Integer)
        Dim t As Integer = a
        a = b
        b = t
    End Sub

    Sub Main()
        Dim x As Integer = 1
        Dim y As Integer = 2

        Console.WriteLine("pre: x = " & x & ", y = " & y)
        Swap(x, y)
        Console.WriteLine("post: x = " & x & ", y = " & y)
    End Sub
End Module
```

The output of the program is:

```
pre: x = 1, y = 2
post: x = 2, y = 1
```

For the invocation of method `Swap` in class `Main`, `a` represents `x`, and `b` represents `y`. Thus, the invocation has the effect of swapping the values of `x` and `y`.

In a method that takes reference parameters, it is possible for multiple names to represent the same storage location:

```
Module Test
    Private s As String

    Sub F(ByRef a As String, ByRef b As String)
        s = "One"
        a = "Two"
        b = "Three"
    End Sub

    Sub G()
        F(s, s)
    End Sub
End Module
```

In the example the invocation of method `F` in `G` passes a reference to `s` for both `a` and `b`. Thus, for that invocation, the names `s`, `a`, and `b` all refer to the same storage location, and the three assignments all modify the instance variable `s`.

If the type of the variable being passed to a reference parameter is not compatible with the reference parameter's type, or if a non-variable is passed as an argument to a reference parameter, a temporary variable may be allocated and passed to the reference parameter. The value being passed in will be copied into this temporary variable before the method is invoked and will be copied back to the original variable (if there is one) when the method returns. Thus, a reference parameter may not necessarily contain a reference to the exact storage of the variable being passed in, and any changes to the reference parameter may not be

reflected in the variable until the method exits. For example:

```
Class Base
End Class

Class Derived
    Inherits Base
End Class

Module Test
    Sub F(ByRef b As Base)
        b = New Base()
    End Sub

    Property G() As Base
        Get
        End Get
        Set
        End Set
    End Property

    Sub Main()
        Dim d As Derived

        F(G)   ' OK.
        F(d)   ' Throws TypeMismatchException after F returns.
    End Sub
End Module
```

In the case of the first invocation of `F`, a temporary variable, is created and the value of the property `G` is assigned to it and passed into `F`. Upon return from `F`, the value in the temporary variable is assigned back to the property of `G`. In the second case, another temporary variable is created and the value of `d` is assigned to it and passed into `F`. When returning from `F`, the value in the temporary variable is cast back to the type of the variable, `Derived`, and assigned to `d`. Since the value being passed back cannot be cast to `Derived`, an exception is thrown at run time.

9.2.5.3 Optional Parameters

An optional parameter is declared with the **Optional** modifier. Parameters that follow an optional parameter in the formal parameter list must be optional as well; failure to specify the **Optional** modifier on the following parameters will trigger a compile-time error. An optional parameter must specify a constant expression to be used as a replacement value if no argument is specified. The expression must be implicitly convertible to the type of the parameter, and the result of the conversion must be a constant expression. Consequently, parameters typed as structures cannot be optional parameters. Optional parameters are the only situation in which an initializer on a parameter is valid. The initialization is always done as a part of the invocation expression, not within the method body itself.

```
Imports System

Module Test
    Sub F(ByVal x As Integer, Optional y As Integer = 20)
        Console.WriteLine("x = " & x & ", y = " & y)
    End Sub

    Sub Main()
        F(10)
        F(30,40)
    End Sub
End Module
```

The output of the program is:

```
x = 10, y = 20
x = 30, y = 40
```

Optional parameters may not be specified in delegate or event declarations.

9.2.5.1 Value Parameters | 9.2.5.2 Reference Parameters | 9.2.5.4 ParamArray Parameters | 9.2.2 External Method Declarations | 9.2.5 Method Parameters | Optional (Visual Basic Language Reference) | Optional Arguments (Visual Basic Language Concepts)

9.2.5.4 ParamArray Parameters

ParamArray parameters are declared with the **ParamArray** modifier. If the **ParamArray** modifier is present, the **ByVal** modifier must be specified, and no other parameter may use the **ParamArray** modifier. The **ParamArray** parameter's type must be a one-dimensional array, and it must be the last parameter in the parameter list.

A **ParamArray** parameter represents an indeterminate number of parameters of the type of the **ParamArray**. Within the method itself, a **ParamArray** parameter is treated as its declared type and has no special semantics. A **ParamArray** parameter is implicitly optional, with a default value of an empty one-dimensional array of the type of the **ParamArray**.

A **ParamArray** permits arguments to be specified in one of two ways in a method invocation:

- The argument given for a **ParamArray** can be a single expression of a type that widens to the **ParamArray** type. In this case, the **ParamArray** acts precisely like a value parameter.
- Alternatively, the invocation can specify zero or more arguments for the **ParamArray**, where each argument is an expression of a type that is implicitly convertible to the element type of the **ParamArray**. In this case, the invocation creates an instance of the **ParamArray** type with a length corresponding to the number of arguments, initializes the elements of the array instance with the given argument values, and uses the newly created array instance as the actual argument.

Except for allowing a variable number of arguments in an invocation, a **ParamArray** is precisely equivalent to a value parameter of the same type, as the following example illustrates.

```
Imports System

Module Test
    Sub F(ByVal ParamArray args As Integer)
        Dim i As Integer

        Console.Write("Array contains " & args.Length & " elements:")
        For Each i In args
            Console.Write(" " & i)
        Next i
        Console.WriteLine()
    End Sub

    Sub Main()
        Dim a As Integer() = { 1, 2, 3 }

        F(a)
        F(10, 20, 30, 40)
        F()
    End Sub
End Module
```

The example produces the output

```
Array contains 3 elements: 1 2 3
Array contains 4 elements: 10 20 30 40
Array contains 0 elements:
```

The first invocation of `F` simply passes the array `a` as a value parameter. The second invocation of `F` automatically creates a four-element array with the given element values and passes that array instance as a value parameter. Likewise, the third invocation of `F` creates a zero-element array and passes that instance as a value parameter. The second and third invocations are precisely equivalent to writing:

```
F(New Integer() {10, 20, 30, 40})
F(New Integer() {})
```

ParamArray parameters may not be specified in delegate or event declarations.

9.2.6 Event Handling

Methods can declaratively handle events raised by objects in instance or shared variables. To handle events, a method declaration specifies the **Handles** keyword and lists one or more events. An event in the **Handles** list is specified by two identifiers separated by a period:

- The first identifier must be an instance or shared variable in the containing type that specifies the **WithEvents** modifier or the **MyBase** keyword; otherwise, a compile-time error occurs. This variable contains the object that will raise the events handled by this method.
- The second identifier must specify a member of the type of the first identifier. The member must be an event, and may be shared. If a shared variable is specified for the first identifier, then the event must be shared, or an error results.

For a handler to be valid, the handled event's parameter types must exactly match those of the event handler. A single member can handle multiple matching events, and multiple methods may handle a single event. A method's accessibility has no effect on its ability to handle events. The following example shows how a method can handle events:

```
Imports System

Class Raiser
    Public Event Constructed()

    Public Sub New()
        RaiseEvent Constructed
    End Sub
End Class

Module Test
    Private WithEvents x As Raiser

    Public Sub Constructed() Handles x.Constructed
        Console.WriteLine("Constructed")
    Public End Sub

    Public Sub Main()
        x = New Raiser()
        x = New Raiser()
    End Sub
End Module
```

This will print out:

```
Constructed
Constructed
```

A type inherits all event handlers provided by its base type. A derived type cannot in any way alter the event mappings it inherits from its base types, but may add additional handlers to the event.

```
HandlesClause ::= [ Handles EventHandlesList ]
EventHandlesList ::=
   EventMemberSpecifier |
   EventHandlesList , EventMemberSpecifier
EventMemberSpecifier ::=
   Identifier . Identifier
   MyBase . Identifier
```

9.3 Constructors

Constructors are special methods that allow control over initialization. They are run after the program begins or when an instance of a type is created. Unlike other members, constructors are not inherited and do not introduce a name into a type's declaration space. Constructors may only be invoked by object-creation expressions or by the .NET Framework; they may never be directly invoked.

```
ConstructorMemberDeclaration ::=
   [ Attributes ] [ ConstructorModifier+ ] Sub New
      [ ( [ ParameterList ] ) ] LineTerminator
   [ Block ]
   End Sub LineTerminator
ConstructorModifier ::= AccessModifier | Shared
```

See Also

9.3.1 Instance Constructors | 9.3.2 Shared Constructors | 9.2 Methods | 9.4 Events | 9.5 Constants |
9.6 Instance and Shared Variables | 9.7 Properties | Using Constructors and Destructors (Visual Basic Language Concepts)

9.3.1 Instance Constructors

Instance constructors initialize instances of a type and are run by the .NET Framework when an instance is created. The parameter list of a constructor is subject to the same rules as the parameter list of a method. Instance constructors may be overloaded.

All constructors in reference types must invoke another constructor. If the invocation is explicit, it must be the first statement in the constructor method body. The statement can either invoke another of the type's instance constructors — for example, `Me.New(...)` or `MyClass.New(...)` — or if it is not a structure it can invoke an instance constructor of the type's base type — for example, `MyBase.New(...)`. It is invalid for a constructor to invoke itself. If a constructor omits a call to another constructor, `MyBase.New()` is implicit. If there is no parameterless base type constructor, a compile-time error occurs. Because **Me** is not considered to be constructed until after the call to a base class constructor, the parameters to a constructor invocation statement cannot reference **Me**, **MyClass**, or **MyBase** implicitly or explicitly.

When a constructor's first statement is of the form `MyBase.New(...)`, the constructor implicitly performs the initializations specified by the variable initializers of the instance variables declared in the type. This corresponds to a sequence of assignments that are executed immediately after invoking the direct base type constructor. Such ordering ensures that all base instance variables are initialized by their variable initializers before any statements that have access to the instance are executed. For example:

```
Imports System

Class A
    Protected x As Integer = 1
End Class

Class B
    Inherits A

    Private y As Integer = x

    Public Sub New()
        Console.WriteLine("x = " & x & ", y = " & y)
    End Sub
End Class
```

When `New B()` is used to create an instance of `B`, the following output is produced:

```
x = 1, y = 1
```

The value of `y` is `1` because the variable initializer is executed after the base class constructor is invoked. Variable initializers are executed in the textual order they appear in the type declaration.

When a type declares only **Private** constructors, it is not possible in general for other types to derive from the type or create instances of the type; the only exception is types nested within the type. **Private** constructors are commonly used in types that contain only **Shared** members.

If a type contains no instance constructor declarations, a default constructor is automatically provided. The default constructor simply invokes the parameterless constructor of the direct base type. If the direct base type does not have an accessible parameterless constructor, a compile-time error occurs. The declared access type for the default constructor is always **Public**.

In the following example a default constructor is provided because the class contains no constructor declarations:

```
Class Message
    Private sender As Object
    Private text As String
End Class
```

Thus, the example is precisely equivalent to the following:

```
Class Message
    Private sender As Object
    Private text As String
```

```
    Public Sub New()
    End Sub
End Class
```

See Also

9.3.2 Shared Constructors | 9.3 Constructors | Using Constructors and Destructors (Visual Basic Language Concepts)

9.3.2 Shared Constructors

Shared constructors initialize a type's shared variables; they are run after the program begins executing, but before any references to a member of the type. A shared constructor specifies the **Shared** modifier, unless it is in a standard module in which case the **Shared** modifier is implied.

Unlike instance constructors, shared constructors have implicit public access, have no parameters, and may not call other constructors. Before the first statement in a shared constructor, the shared constructor implicitly performs the initializations specified by the variable initializers of the shared variables declared in the type. This corresponds to a sequence of assignments that are executed immediately upon entry to the constructor. The variable initializers are executed in the textual order they appear in the type declaration.

The following example shows an `Employee` class with a shared constructor that initializes a shared variable:

```
Imports System.Data

Class Employee
    Private Shared ds As DataSet

    Shared Sub New()
        ds = New DataSet()
    End Sub

    Public Name As String
    Public Salary As Decimal
End Class
```

Exactly when shared constructors are run is mostly implementation dependent, though several guarantees are provided if a shared constructor is explicitly defined:

- Shared constructors are run before any instance of a class type is created.
- Shared constructors are run before any instance members of a structure type are accessed, or before any constructor of a structure type is explicitly called. Calling the implicit parameterless constructor created for structures will not cause the shared constructor to run.
- Shared constructors are run before any of the type's shared members are referenced.
- Shared constructors are run before any types that derive from the type are loaded.
- A shared constructor will not be run more than once during a single execution of a program.

The above guarantees do not apply in the situation where a shared constructor is implicitly created for shared initializers. The output from the following example is uncertain, because the exact ordering of loading and therefore of shared constructor execution is not defined:

```
Imports System

Module Test
    Sub Main()
        A.F()
        B.F()
    End Sub
End Module

Class A
    Shared Sub New()
        Console.WriteLine("Init A")
    End Sub

    Public Shared Sub F()
        Console.WriteLine("A.F")
    End Sub
End Class

Class B
    Shared Sub New()
```

```
        Console.WriteLine("Init B")
    End Sub

    Public Shared Sub F()
        Console.WriteLine("B.F")
    End Sub
End Class
```

The output could be either of the following:

```
Init A
A.F
Init B
B.F
```

or

```
Init B
Init A
A.F
B.F
```

By contrast, the following example produces predictable output, because the **Shared** constructor for the class `A` must execute before the **Shared** constructor for the class `B`, which derives from it:

```
Imports System

Module Test
    Sub Main()
        Console.WriteLine("1")
        B.G()
        Console.WriteLine("2")
    End Sub
End Module

Class A
    Shared Sub New()
        Console.WriteLine("Init A")
    End Sub
End Class

Class B
    Inherits A

    Shared Sub New()
        Console.WriteLine("Init B")
    End Sub

    Public Shared Sub G()
        Console.WriteLine("B.G")
    End Sub
End Class
```

The output is:

```
Init A
Init B
B.G
```

It is also possible to construct circular dependencies that allow **Shared** variables with variable initializers to be observed in their default value state, as in the following example:

```
Class A
```

```
    Public Shared X As Integer = B.Y + 1
End Class

Class B
    Public Shared Y As Integer = A.X + 1

    Shared Sub Main()
        Console.WriteLine("X = " & A.X & ", Y = " & B.Y)
    End Sub
End Class
```

This produces the output:

```
X = 1, Y = 2
```

To execute the `Main` method, the system first loads class `B`. The **Shared** constructor of class `B` proceeds to compute the initial value of `Y`, which recursively causes class `A` to be loaded because the value of `A.X` is referenced. The **Shared** constructor of class `A` in turn proceeds to compute the initial value of `X`, and in doing so fetches the *default* value of `Y`, which is zero. `A.X` is thus initialized to `1`. The process of loading `A` then completes, returning to the calculation of the initial value of `Y`, the result of which becomes `2`.

Had the `Main` method instead been located in class `A`, the example would have produced the following output:

```
X = 2, Y = 1
```

Avoid circular references in **Shared** variable initializers since it is generally impossible to determine the order in which classes containing such references are loaded.

9.3.1 Instance Constructors | 9.3 Constructors | Using Constructors and Destructors (Visual Basic Language Concepts)

9.4 Events

Events are used to notify code of a particular occurrence. An event declaration consists of an identifier, either a delegate type or a parameter list, and an optional **Implements** clause. If a delegate type is specified, the delegate type may not have a return type. If a parameter list is specified, it may not contain **Optional** or **ParamArray** parameters. The accessibility domain of the parameter types and/or delegate type must be the same as, or a superset of, the accessibility domain of the event itself. Events may be shared by specifying the **Shared** modifier.

In addition to the member name added to the type's declaration space, an event declaration implicitly declares several other members. Given an event named `X`, the following members are added to the declaration space:

- If the form of the declaration is a method declaration, a nested delegate class named `XEventHandler` is introduced. The nested delegate class matches the method declaration and has the same accessibility as the event. The attributes in the parameter list apply to the parameters of the delegate class.
- A **Private** instance variable typed as the delegate, named `XEvent`.
- A method named `add_X`, which takes the delegate type and has the same access type as the event.
- A method named `remove_X`, which takes the delegate type and has the same access type as the event.

If a type attempts to declare a name that matches one of the above names, a compile-time error will result. It is not possible to override or overload any of the introduced members, although it is possible to shadow them in derived types. For example, the class declaration

```
Class Raiser
    Public Event Constructed(ByVal i As Integer)
End Class
```

is equivalent to the following declaration

```
Class Raiser
    Public Delegate Sub ConstructedEventHandler(ByVal i As Integer)

    Protected ConstructedEvent As ConstructedEventHandler

    Public Sub add_Constructed(ByVal d As ConstructedEventHandler)
        ConstructedEvent = _
            CType( _
                ConstructedEvent.Combine(ConstructedEvent, d), _
                    Raiser.ConstructedEventHandler)
    End Sub

    Public Sub remove_Constructed(ByVal d As ConstructedEventHandler)
        ConstructedEvent = _
            CType( _
                ConstructedEvent.Remove(ConstructedEvent, d), _
                    Raiser.ConstructedEventHandler)
    End Sub
End Class
```

Declaring an event without specifying a delegate type is the simplest and most compact syntax, but has the disadvantage of declaring a new delegate type for each event. For example, in the following example, three hidden delegate types are created, even though all three events have the same parameter list:

```
Public Class Button
    Public Event Click(sender As Object, e As System.EventArgs)
    Public Event DoubleClick(sender As Object, e As System.EventArgs)
    Public Event RightClick(sender As Object, e As System.EventArgs)
End Class
```

In the following example, the events simply use the same delegate, `EventHandler`:

```
Delegate Sub EventHandler(sender As Object, e As System.EventArgs)
```

```
Public Class Button
    Public Event Click As EventHandler
    Public Event DoubleClick As EventHandler
    Public Event RightClick As EventHandler
End Class
```

Events can be handled in one of two ways: statically or dynamically. Statically handling events is simpler and only requires a **WithEvents** variable and a **Handles** clause. In the following example, class `Form1` statically handles the event `Click` of object `Button`:

```
Imports System

Public Class Form1
    Public WithEvents Button1 As Button = New Button()
    Public Sub Button1_Click(sender As Object, e As System.EventArgs) _
           Handles Button1.Click
        Console.WriteLine("Button1 was clicked!")
    End Sub
End Class
```

Dynamically handling events is more complex because the event must be explicitly connected and disconnected to in code. The statement `AddHandler` adds a handler for an event, and the statement `RemoveHandler` removes a handler for an event. The next example shows a class `Form1` that adds `Button1_Click` as an event handler for `Button1`'s `Click` event:

```
Imports System

Public Class Form1
    Public Sub New()
        ' Add Button1_Click as an event handler for Button1's Click event.
        AddHandler Button1.Click , AddressOf Button1_Click
    End Sub

    Private Button1 As Button = New Button()

    Sub Button1_Click(sender As Object, e As EventArgs)
        Console.WriteLine("Button1 was clicked!")
    End Sub

    Public Sub Disconnect()
        RemoveHandler Button1.Click, AddressOf Button1_Click
    End Sub
End Class
```

In method `Disconnect`, the event handler is removed.

```
EventMemberDeclaration ::=
   [ Attributes ] [ EventModifiers+ ] Event Identifier ParametersOrType
      [ ImplementsClause ] LineTerminator
ParametersOrType ::=
   [ ( [ ParameterList ] ) ] |
   As TypeName
EventModifiers ::= AccessModifier | Shadows | Shared
```

9.5 Constants

A *constant* is a constant value that is a member of a type. Constants are implicitly shared. If the declaration contains an **As** clause, the clause specifies the type of the member introduced by the declaration. If the type is omitted and strict semantics are being used, a compile-time error occurs; otherwise the type of the constant is implicitly **Object**. The type of a constant may only be a primitive type or **Object**. If a constant is typed as **Object** and there is no type character, the real type of the constant will be the type of the constant expression. Otherwise, the type of the constant is the type of the constant's type character.

The following example shows a class named `Constants` that has two public constants:

```
Class Constants
    Public A As Integer = 1
    Public B As Integer = A + 1
End Class
```

Constants can be accessed through the class, as in the following example, which prints out the values of `Constants.A` and `Constants.B`.

```
Module Test
    Sub Main()
        Console.WriteLine(Constants.A & ", " & Constants.B)
    End Sub
End Module
```

A constant declaration that declares multiple constants is equivalent to multiple declarations of single constants. The following example declares three constants in one declaration statement.

```
Class A
    Protected Const x As Integer = 1, y As Long = 2, z As Short = 3
End Class
```

This declaration is equivalent to the following:

```
Class A
    Protected Const x As Integer = 1
    Protected Const y As Long = 2
    Protected Const z As Short = 3
End Class
```

The accessibility domain of the type of the constant must be the same as or a superset of the accessibility domain of the constant itself. The constant expression must yield a value of the constant's type or of a type that is implicitly convertible to the constant's type. The constant expression may not be circular; that is, a constant may not be defined in terms of itself.

The compiler automatically evaluates the constant declarations in the appropriate order. In the following example, the compiler first evaluates `Y`, then `Z`, and finally `X`, producing the values 10, 11, and 12, respectively.

```
Class A
    Public Const X As Integer = B.Z + 1
    Public Const Y As Integer = 10
End Class

Class B
    Public Const Z As Integer = A.Y + 1
End Class
```

When a symbolic name for a constant value is desired, but the type of the value is not permitted in a constant declaration or when the value cannot be computed at compile time by a constant expression, a read-only variable may be used instead.

```
ConstantMemberDeclaration ::=
   [ Attributes ] [ ConstantModifier+ ] Const
      ConstantDeclarators LineTerminator
```

```
ConstantModifier ::= AccessModifier | Shadows
ConstantDeclarators ::=
   ConstantDeclarator |
   ConstantDeclarators , ConstantDeclarator
ConstantDeclarator ::= Identifier [ As TypeName ] =
   ConstantExpression LineTerminator
```

9.6 Instance and Shared Variables

An instance or shared variable is a member of a type that can store information. The **Dim** modifier must be specified if no modifiers are specified, but may be omitted otherwise. A single variable declaration may include multiple variable declarators; each variable declarator introduces a new instance or shared member. If an initializer is specified, only one instance or shared variable may be declared by the variable declarator.

A variable declared with the **Shared** modifier is a *shared variable*. A shared variable identifies exactly one storage location regardless of the number of instances of the type that are created. A shared variable comes into existence when a program begins executing, and ceases to exist when the program terminates.

A variable declared without the **Shared** modifier is called an *instance variable*. Every instance of a class contains a separate copy of all instance variables of the class. An instance variable of a reference type comes into existence when a new instance of that type is created, and ceases to exist when there are no references to that instance and the **Finalize** method has executed. An instance variable of a value type has exactly the same lifetime as the variable to which it belongs. In other words, when a variable of a value type comes into existence or ceases to exist, so does the instance variable of the value type.

If the declarator contains an **As** clause, the clause specifies the type of the members introduced by the declaration. If the type is omitted and strict semantics are being used, a compile-time error occurs. Otherwise the type of the members is implicitly **Object** or the type of the members' type character.

> **Note** There is no ambiguity in the syntax: if a declarator omits a type, it will always use the type of a following declarator.

The accessibility domain of an instance or shared variable's type or array element type must be the same as or a superset of the accessibility domain of the instance or shared variable itself.

The following example shows a `Color` class that has internal instance variables named `redPart`, `greenPart`, and `bluePart`:

```
Class Color
    Friend redPart As Short
    Friend bluePart As Short
    Friend greenPart As Short

    Public Sub New(red As Short, blue As Short, green As Short)
        redPart = red
        bluePart = blue
        greenPart = green
    End Sub
End Class
```

```
VariableMemberDeclaration ::=
   [ Attributes ] [ VariableModifier+ ] [ Dim ] VariableDeclarators
      LineTerminator
VariableModifier ::=
   AccessModifier |
   Shadows |
   Shared |
   ReadOnly |
   WithEvents
VariableDeclarators ::=
   VariableDeclarator |
   VariableDeclarators , VariableDeclarator
VariableDeclarator ::=
   VariableIdentifiers [ As TypeName ] |
   VariableIdentifier [ As [ New ] TypeName [ ( ArgumentList ) ] ]
      [ = VariableInitializer ]
VariableIdentifiers ::=
   VariableIdentifier |
   VariableIdentifiers , VariableIdentifier
VariableIdentifier ::= Identifier [ ArrayNameModifier ]
```

Declarations and Constants Summary (Visual Basic Language Reference) | Variables (Visual Basic Language Concepts)

9.6.1 Read-Only Variables

When an instance or shared variable declaration includes a **ReadOnly** modifier, assignments to the variables introduced by the declaration may only occur as part of the declaration or in a constructor in the same class. Specifically, assignments to a read-only instance or shared variable are permitted only in the following situations:

- In the variable declaration that introduces the instance or shared variable (by including a variable initializer in the declaration).
- For an instance variable, in the instance constructors of the class that contains the variable declaration. The instance variable can only be accessed in an unqualified manner or through **Me** or **MyClass**.
- For a shared variable, in the shared constructor of the class that contains the shared variable declaration.

A shared read-only variable is useful when a symbolic name for a constant value is desired, but when the type of the value is not permitted in a constant declaration, or when the value cannot be computed at compile time by a constant expression.

An example of the first such application follows, in which color shared variables are declared **ReadOnly** to prevent them from being changed by other programs:

```
Class Color
    Friend redPart As Short
    Friend bluePart As Short
    Friend greenPart As Short

    Public Sub New(red As Short, blue As Short, green As Short)
        redPart = red
        bluePart = blue
        greenPart = green
    End Sub

    Public Shared ReadOnly Red As Color = New Color(&HFF, 0, 0)
    Public Shared ReadOnly Blue As Color = New Color(0, &HFF, 0)
    Public Shared ReadOnly Green As Color = New Color(0, 0, &HFF)
    Public Shared ReadOnly White As Color = New Color(&HFF, &HFF, &HFF)
End Class
```

Constants and read-only shared variables have different semantics. When an expression references a constant, the value of the constant is obtained at compile time, but when an expression references a read-only shared variable, the value of the shared variable is not obtained until run time. Consider the following application, which consists of two separate programs.

file1.vb:

```
Namespace Program1
    Public Class Utils
        Public Shared ReadOnly X As Integer = 1
    End Class
End Namespace
```

file2.vb:

```
Imports System

Namespace Program2
    Module Test
        Sub Main()
            Console.WriteLine(Program1.Utils.X)
        End Sub
    End Module
End Namespace
```

The namespaces `Program1` and `Program2` denote two programs that are compiled separately. Because variable `Program1.Utils.X` is declared as **Shared ReadOnly**, the value output by the `Console.WriteLine` statement is not known at compile time, but rather is obtained at run time. Thus, if the value of `X` is changed and `Program1` is recompiled, the `Console.WriteLine` statement will

output the new value even if `Program2` is not recompiled. However, if `X` had been a constant, the value of `X` would have been obtained at the time `Program2` was compiled, and would have remained unaffected by changes in `Program1` until `Program2` was recompiled.

9.6.2 WithEvents Variables

A type can declare that it handles some set of events raised by one of its instance or shared variables by declaring the instance or shared variable that raises the events with the **WithEvents** modifier. For example:

```
Imports System

Class Raiser
    Public Event Constructed()

    Public Sub New()
        RaiseEvent Constructed
    End Sub
End Class

Module Test
    Private WithEvents x As Raiser

    Private Sub HandleConstructed() Handles x.Constructed
        Console.WriteLine("Constructed")
    End Sub

    Public Sub Main()
        x = New Raiser()
    End Sub
End Module
```

In this example, the method `HandleConstructed` handles the event `Constructed` that is raised by the instance of the type `Raiser` stored in the instance variable `x`.

The **WithEvents** modifier causes the variable to be renamed with a leading underscore and replaced with a property of the same name that does the event hookup. For example, if the variable's name is `F`, it is renamed to `_F` and a property `F` is implicitly declared. If there is a collision between the variable's new name and another declaration, a compile-time error will be reported.

The implicit property created by a **WithEvents** declaration takes care of hooking and unhooking the relevant event handlers. When a value is assigned to the variable, the property first calls the `remove` method for the event on the instance currently in the variable (unhooking the existing event handler, if any). Next the assignment is made, and the property calls the `add` method for the event on the new instance in the variable (hooking up the new event handler). The following code is equivalent to the code above for the standard module `Test`:

```
Module Test
    Private _x As Raiser

    Public Property x() As Raiser
        Get
            Return _x
        End Get

        Set (ByVal Value As Raiser)
            ' Unhook any existing handlers.
            If Not _x Is Nothing Then
                RemoveHandler _x.Constructed, AddressOf HandleConstructed
            End If

            ' Change value.
            _x = Value

            ' Hook-up new handlers.
            If Not _x Is Nothing Then
                AddHandler _x.Constructed, AddressOf HandleConstructed
            End If
        End Set
    End Property

    Sub HandleConstructed()
```

```
        Console.WriteLine("Constructed")
    End Sub

    Sub Main()
        x = New Raiser()
    End Sub
End Module
```

It is not valid to declare an instance or shared variable as **WithEvents** if it does not raise any events or if the variable is typed as a structure. In addition, **WithEvents** may not be specified in a structure, and **WithEvents** and **ReadOnly** cannot be combined.

See Also

9.6.3 Variable Initializers

Instance and shared variable declarations in classes (but not structures) may include variable initializers. For **Shared** variables, variable initializers correspond to assignment statements that are executed after the program begins, but before the **Shared** variable is first referenced. For instance variables, variable initializers correspond to assignment statements that are executed when an instance of the class is created. Structures cannot have variable initializers because their parameterless constructors cannot be modified.

Consider the following example:

```
Imports System

Class Test
    Public Shared x As Double = Math.Sqrt(2.0)
    Public i As Integer = 100
    Public s As String = "Hello"
End Class

Module TestModule
    Sub Main()
        Dim a As Test = New Test()

        Console.WriteLine("x = " & x & ", i = " & a.i & ", s = " & a.s)
    End Sub
End Module
```

The example produces the following output:

```
x = 1.414213562373095, i = 100, s = Hello
```

An assignment to `x` occurs when the class is loaded, and assignments to `i` and `s` occur when a new instance of the class is created.

It is useful to think of variable initializers as assignment statements that are automatically inserted in the block of the type's constructor. The following example contains several instance variable initializers.

```
Imports System.Collections

Class A
    Private x As Integer = 1
    Private y As Integer = -1
    Private count As Integer

    Public Sub New()
        count = 0
    End Sub

    Public Sub New(n As Integer)
        count = n
    End Sub
End Class

Class B
    Inherits A

    Private sqrt2 As Double = Math.Sqrt(2.0)
    Private items As ArrayList = New ArrayList(100)
    Private max As Integer

    Public Sub New()
        Me.New(100)
        items.Add("default")
    End Sub

    Public Sub New(n As Integer)
```

```
        MyBase.New(n – 1)
        max = n
    End Sub
End Class
```

The example corresponds to the code shown below, where each comment indicates an automatically inserted statement.

```
Imports System.Collections

Class A
    Private x, y, count As Integer

    Public Sub New()
        MyBase.New ' Invoke object() constructor.
        x = 1 ' This is a variable initializer.
        y = -1 ' This is a variable initializer.
        count = 0
    End Sub

    Public Sub New(n As Integer)
        MyBase.New ' Invoke object() constructor.
        x = 1 ' This is a variable initializer.
        y = - 1 ' This is a variable initializer.
        count = n
    End Sub
End Class

Class B
    Inherits A

    Private sqrt2 As Double
    Private items As ArrayList
    Private max As Integer

    Public Sub New()
        Me.New(100)
        items.Add("default")
    End Sub

    Public Sub New(n As Integer)
        MyBase.New(n - 1)
        sqrt2 = Math.Sqrt(2.0) ' This is a variable initializer.
        items = New ArrayList(100) ' This is a variable initializer.
        max = n
    End Sub
End Class
```

All variables are initialized to the default value of their type before any variable initializers are executed. For example:

```
Imports System

Class Test
    Public Shared b As Boolean
    Public i As Integer
End Class

Module TestModule
    Sub Main()
        Dim t As Test = New Test()
        Console.WriteLine("b = " & b & ", i = " & t.i)
    End Sub
End Module
```

Because `b` is automatically initialized to its default value when the class is loaded and `i` is automatically initialized to its default value when an instance of the class is created, the preceding code produces the following output:

```
b = False, i = 0
```

Each variable initializer must yield a value of the variable's type or of a type that is implicitly convertible to the variable's type. A variable initializer may be circular or refer to a variable that will be initialized after it, in which case the value of the referenced variable is its default value for the purposes of the initializer. Such an initializer is of dubious value.

There are four forms of variable initializers: regular initializers, array-element initializers, array-size initializers, and object initializers. The first two forms appear after an equal sign that follows the type name, the latter two are part of the declaration itself. Only one form of initializer may be used on any particular declaration.

```
VariableInitializer ::= RegularInitializer | ArrayElementInitializer
```

See Also

9.6.3.1 Regular Initializers | 9.6.3.4 Array-Element Initializers | 9.6.3.3 Array-Size Initializers | | 9.6.1 Read-Only Variables | 9.6.2 WithEvents Variables | 9.6 Instance and Shared Variables | 4.6 Accessibility | 4.3.3 Shadowing | Declarations and Constants Summary (Visual Basic Language Reference) | Variables (Visual Basic Language Concepts)

9.6.3.1 Regular Initializers

A regular initializer is an expression that is implicitly convertible to the type of the variable. It appears after an equal sign that follows the type name and must be classified as a value. For example:

```
Imports System

Module Test
    Dim x As Integer = 10
    Dim y As Integer = 20

    Sub Main()
        Console.WriteLine("x = " & x & ", y = " & y)
    End Sub
End Module
```

This program produces the output:

```
x = 10, y = 20
```

```
RegularInitializer ::= Expression
```

See Also

9.6.3.4 Array-Element Initializers | 9.6.3.3 Array-Size Initializers | | 9.6.3 Variable Initializers | 4.6 Accessibility | 4.3.3 Shadowing | 9.6 Instance and Shared Variables | 9.6.1 Read-Only Variables | 9.6.2 WithEvents Variables | 11. Expressions | Declarations and Constants Summary (Visual Basic Language Reference) | Variables (Visual Basic Language Concepts)

9.6.3.2 Object Initializers

An object initializer is specified using the **New** keyword before the type name and an optional parameter list after the type name. An object initializer is equivalent to a regular initializer of the form `= New T(A)`, where `T` is the type name and `A` is the supplied formal parameter list, if any. So

```
Module TestModule
    Sub Main()
        Dim x As New Test(10)
    End Sub
End Module
```

is equivalent to

```
Module TestModule
    Sub Main()
        Dim x As Test = New Test(10)
    End Sub
End Module
```

The parenthesis in an object initializer is always interpreted as the parameters to the constructor and never as array type modifiers.

9.6.3.3 Array-Size Initializers

An array-size initializer is a modifier on the name of the variable that gives a set of dimension upper bounds denoted by expressions. For shared and instance variables, the upper-bound expressions must be constant; otherwise the expressions must be classified as values. The upper bound expressions must be implicitly convertible to **Integer**. The set of upper bounds is equivalent to a variable initializer of an array-creation expression with the given upper bounds. The number of dimensions of the array type is inferred from the array size initializer. So

```
Module Test
    Sub Main()
        Dim x(5, 10) As Integer
    End Sub
End Module
```

is equivalent to

```
Module Test
    Sub Main()
        Dim x As T(,) = new Integer(5, 10) {}
    End Sub
End Module
```

All upper bounds must be equal to or greater than -1, and all dimensions must have an upper bound specified. If the element type of the array being initialized is itself an array type, the array-type modifiers go to the right of the array-size initializer. For example

```
Module Test
    Sub Main()
        Dim x(5,10)(,,) As Integer
    End Sub
End Module
```

declares a local variable `x` whose type is a two-dimensional array of three-dimensional arrays of **Integer**, initialized to an array with bounds of `0..5` in the first dimension and `0..10` in the second dimension. It is not possible to use an array size initializer to initialize the elements of a variable whose type is an array of arrays.

If an array element initializer is specified, each expression in the upper bound list must be a constant expression. Furthermore, the rank and dimension lengths specified by the rank initialization list must match those of the array element initializer. A variable declaration may not include both an array type modifier on its type and an array-size initializer.

```
ArraySizeInitializationModifier ::=
   ( UpperBoundList ) [ ArrayTypeModifiers ]
UpperBoundList::=
   Expression |
   UpperBoundList , Expression
```

See Also

9.6.3.1 Regular Initializers | 9.6.3.4 Array-Element Initializers | 9.6.3.2 Object Initializers | 4.6 Accessibility | 4.3.3 Shadowing | 9.6 Instance and Shared Variables | 9.6.1 Read-Only Variables | 9.6.2 WithEvents Variables | 9.6.3 Variable Initializers | 11. Expressions | Declarations and Constants Summary (Visual Basic Language Reference) | Variables (Visual Basic Language Concepts)

9.6.3.4 Array-Element Initializers

An array-element initializer consists of a sequence of variable initializers, enclosed by curly braces ({}) and separated by commas. Each variable initializer is an expression or, in the case of a multidimensional array, a nested array-element initializer. Each expression must be classified as a value. Array-element initializers may also be used in array-creation expressions.

The type of expression or statement in which an array-element initializer is used determines the type of the array being initialized. In an array-creation expression, the array type immediately precedes the initializer. In a variable declaration, the array type is the type of the variable being declared. When an array-element initializer is used in a variable declaration, such as:

```
Private a As Integer() = { 0, 2, 4, 6, 8 }
```

it is simply shorthand for an equivalent array-creation expression:

```
Private a As Integer() = New Integer() { 0, 2, 4, 6, 8 }
```

In an array-element initializer, the outermost nesting level corresponds to the leftmost dimension, and the innermost nesting level corresponds to the rightmost dimension. The initializer must have the same number levels of nesting as there are dimensions in the array. All of the elements in the innermost nesting level must be implicitly convertible to the element type of the array. The number of elements in each nested array-element initializer must always be consistent with the size of the other array-element initializers at the same level.

The following example creates a two-dimensional array with a length of five for the leftmost dimension and a length of two for the rightmost dimension:

```
Module Test
    Sub Main()
        Dim b As Integer(,) = _
            { { 0, 1 }, { 2, 3 }, { 4, 5 }, { 6, 7 }, { 8, 9 } }
    End Sub
End Module
```

The example is equivalent to the following:

```
Module Test
    Sub Main()
        Private b(4, 1) As Integer

        b(0, 0) = 0: b(0, 1) = 1
        b(1, 0) = 2: b(1, 1) = 3
        b(2, 0) = 4: b(2, 1) = 5
        b(3, 0) = 6: b(3, 1) = 7
        b(4, 0) = 8: b(4, 1) = 9
    End Sub
End Module
```

If the array-creation expression specifies the bounds of the dimensions, the number of elements at any particular level must be the same as the size of the corresponding dimension. If the bounds are unspecified, the length of each dimension is the number of elements in the corresponding level of nesting.

Some valid and invalid examples follow:

```
' OK.
Private x() As Integer = New Integer(2) {0, 1, 2}
' Error, length/initializer mismatch.
Private y() As Integer = New Integer(2) {0, 1, 2, 3}
```

Here, the initializer for `y` is in error because the length and the number of elements in the initializer do not agree.

An empty array-element initializer (that is, one that contains curly braces but no initializer list) is always valid regardless of the number of dimensions of the array. If the size of the dimensions of the array being initialized is known in an array-creation

expression, the empty array-element initializer represents an array instance of the specified size where all the elements have been initialized to the element type's default value. If the dimensions of the array being initialized are not known, the empty array-element initializer represents an array instance in which all dimensions are size zero.

Because context is required to determine the type of an array initializer, it is not possible to use an array initializer in an expression context. Therefore, the following code is not valid:

```
Module Test
    Sub F(ByVal a() As Integer)
    End Sub

    Sub Main()
        ' Error, can't use without array creation expression.
        F({1, 2, 3})

        ' OK.
        F(New Integer() {1, 2, 3})
    End Sub
End Module
```

At run time, the expressions in an array-element initializer are evaluated in textual order from left to right.

```
ArrayElementInitializer ::= { [ VariableInitializerList ] }
VariableInitializerList ::=
   VariableInitializer |
   VariableInitializerList , VariableInitializer
VariableInitializer ::= Expression | ArrayElementInitializer
```

9.6.4 System.MarshalByRefObject Classes

Classes that derive from the class **System.MarshalByRefObject** are marshaled across context boundaries using proxies (that is, by reference) rather than through copying (that is, by value). This means that an instance of such a class may not be a true instance but instead may just be a stub that marshals variable accesses and method calls across a context boundary.

As a result, it is not possible to create a reference to the storage location of variables defined on such classes. This means that variables typed as classes derived from **System.MarshalByRefObject** cannot be passed to reference parameters, and methods and variables of variables typed as value types may not be accessed. Instead, Visual Basic .NET treats variables defined on such classes as if they were properties (since the restrictions are the same on properties).

There is one exception to this rule: a member implicitly or explicitly qualified with **Me** is exempt from the above restrictions, because **Me** is always guaranteed to be an actual object, not a proxy.

9.7 Properties

Properties are a natural extension of variables; both are named members with associated types, and the syntax for accessing variables and properties is the same. Unlike variables, however, properties do not denote storage locations. Instead, properties have *accessors*, which specify the statements to execute in order to read or write their values.

Properties are defined with property declarations. The first part of a property declaration resembles a field declaration. The second part includes a **Get** accessor and/or a **Set** accessor. In the example below, the `Button` class defines a `Caption` property.

```
Public Class Button
    Private captionValue As String

    Public Property Caption() As String
        Get
            Return captionValue
        End Get

        Set (ByVal Value As String)
            captionValue = value
            Repaint()
        End Set
    End Property
End Class
```

Based on the `Button` class above, the following is an example of use of the `Caption` property:

```
Dim okButton As Button = New Button()

okButton.Caption = "OK" ' Invokes Set accessor.
Dim s As String = okButton.Caption ' Invokes Get accessor.
```

Here, the **Set** accessor is invoked by assigning a value to the property, and the **Get** accessor is invoked by referencing the property in an expression.

If no type is specified for a property and strict semantics are being used, a compile-time error occurs; otherwise the type of the property is implicitly **Object** or the type of the property's type character. A property declaration may contain either a **Get** accessor, which retrieves the value of the property, a **Set** accessor, which stores the value of the property, or both. Because a property implicitly declares methods, a property may be declared with the same modifiers as a method. If the property is defined in an interface or defined with the **MustOverride** modifier, the property body and the **End** construct must be omitted; otherwise, a compile-time error occurs.

The index parameter list makes up the signature of the property, so properties may be overloaded on index parameters but not on the type of the property. The index parameter list is the same as for a regular method. However, none of the parameters may be modified with the **ByRef** modifier and none of them may be named `Value` (which is reserved for the implicit value parameter in the **Set** accessor).

A property may be declared as follows:

- If the property specifies no property type modifier, the property must have both a **Get** accessor and a **Set** accessor. The property is said to be a read-write property.
- If the property specifies the **ReadOnly** modifier, the property must have a **Get** accessor and may not have a **Set** accessor. The property is said to be read-only property. It is a compile-time error for a read-only property to be the target of an assignment.
- If the property specifies the **WriteOnly** modifier, the property must have a **Set** accessor and may not have a **Get** accessor. The property is said to be write-only property. It is a compile-time error to reference a write-only property in an expression except as the target of an assignment or as an argument to a method.

The **Get** and **Set** accessors of a property are not distinct members, and it is not possible to declare the accessors of a property separately. The following example does not declare a single read-write property. Rather, it declares two properties with the same name, one read-only and one write-only:

```
Class A
    Private nameValue As String
```

```
    ' Error, contains a duplicate member name.
    Public ReadOnly Property Name() As String
        Get
            Return nameValue
        End Get
    End Property

    ' Error, contains a duplicate member name.
    Public WriteOnly Property Name() As String
        Set (ByVal Value As String)
            nameValue = value
        End Set
    End Property
End Class
```

Since two members declared in the same class cannot have the same name, the example causes a compile-time error.

When a derived type shadows a property, the derived property hides the shadowed property with respect to both reading and writing. In the following example, the `P` property in `B` hides the `P` property in `A` with respect to both reading and writing:

```
Class A
    Public WriteOnly Property P() As Integer
        Set (ByVal Value As Integer)
        End Set
    End Property
End Class

Class B
    Inherits A

    Public Shadows ReadOnly Property P() As Integer
       Get
       End Get
    End Property
End Class

Module Test
    Sub Main()
        Dim x As B = New B

        B.P = 10     ' Error, B.P is read-only.
    End Sub
End Module
```

The accessibility domain of the return type or parameter types must be the same as or a superset of the accessibility domain of the property itself. A property may only have one **Set** accessor and one **Get** accessor.

Except for differences in declaration and invocation syntax, **Overridable**, **NotOverridable**, **Overrides**, **MustOverride**, and **MustInherit** properties behave exactly like **Overridable**, **NotOverridable**, **Overrides**, **MustOverride**, and **MustInherit** methods. When a property is overridden, the overriding property must be of the same type (read-write, read-only, write-only).

In the following example `X` is an **Overridable** read-only property, `Y` is an **Overridable** read-write property, and `Z` is a **MustOverride** read-write property.

```
MustInherit Class A
    Private y As Integer

    Public Overridable ReadOnly Property X() As Integer
        Get
            Return 0
        End Get
    End Property

    Public Overridable Property Y() As Integer
        Get
            Return y
```

```
         End Get
        Set (ByVal Value As Integer)
            y = value
        End Set
    End Property

    Public MustOverride Property Z() As Integer
End Class
```

Because `Z` is **MustOverride**, the containing class `A` must be declared **MustInherit**.

By contrast, a class that derives from class `A` is shown below:

```
Class B
    Inherits A

    Private zValue As Integer

    Public Overrides ReadOnly Property X() As Integer
        Get
            Return MyBase.X + 1
        End Get
    End Property

    Public Overrides Property Y() As Integer
        Get
            Return MyBase.Y
        End Get
        Set (ByVal Value As Integer)
            If value < 0 Then
                MyBase.Y = 0
            Else
                MyBase.Y = Value
            End If
        End Set
    End Property

    Public Overrides Property Z() As Integer
        Get
            Return zValue
        End Get
        Set (ByVal Value As Integer)
            zValue = Value
        End Set
    End Property
End Class
```

Here, the declarations of properties `X`, `Y`, and `Z` override the base properties. Each property declaration exactly matches the accessibility modifiers, type, and name of the corresponding inherited property. The **Get** accessor of property `X` and the **Set** accessor of property `Y` use the **MyBase** keyword to access the inherited properties. The declaration of property `Z` overrides the **MustOverride** property — thus, there are no outstanding **MustOverride** members in class `B`, and `B` is permitted to be a regular class.

Properties can be used to delay initialization of a resource until the moment it is first referenced. For example:

```
Imports System.IO

Public Class ConsoleStreams
    Private Shared reader As TextReader
    Private Shared writer As TextWriter
    Private Shared errors As TextWriter

    Public Shared ReadOnly Property [In]() As TextReader
        Get
            If reader Is Nothing Then
                reader = New StreamReader(File.OpenStandardInput())
```

```
            End If
            Return reader
        End Get
    End Property

    Public Shared ReadOnly Property Out() As TextWriter
        Get
            If writer Is Nothing Then
                writer = New StreamWriter(File.OpenStandardOutput())
            End If
            Return writer
        End Get
    End Property

    Public Shared ReadOnly Property [Error]() As TextWriter
        Get
            If errors Is Nothing Then
                errors = New StreamWriter(File.OpenStandardError())
            End If
            Return errors
        End Get
    End Property
End Class
```

The `ConsoleStreams` class contains three properties, `In`, `Out`, and `Error`, that represent the standard input, output, and error devices, respectively. By exposing these members as properties, the `ConsoleStreams` class can delay their initialization until they are actually used. For example, upon first referencing the `Out` property, as in `ConsoleStreams.Out.WriteLine("hello, world")`, the underlying `TextWriter` for the output device is created. But if the application makes no reference to the `In` and `Error` properties, then no objects are created for those devices.

```
PropertyMemberDeclaration ::=
   [ Attributes ] [ PropertyModifier+ ] Property Identifier
      [ ( [ ParameterList ] ) ] [ As TypeName ] [ ImplementsClause ]
      LineTerminator
   [ PropertyAccessorDeclaration+ ]
   [ End Property LineTerminator ]
PropertyModifier ::= ProcedureModifier | Default | ReadOnly | WriteOnly
PropertyAccessorDeclaration ::=
   PropertyGetDeclaration |
   PropertySetDeclaration
```

9.7.1 Get Accessor Declarations

A **Get** accessor (getter) is declared by using a property **Get** declaration. A property **Get** declaration consists of the keyword **Get** followed by a statement block. Given a property named `P`, a **Get** accessor declaration implicitly declares a method with the name `get_P` with the same modifiers, type, and parameter list as the property. If the type contains a declaration with that name, a compile-time error results.

A special local variable, which is implicitly declared in the **Get** accessor body's declaration space with the same name as the property, represents the return value of the property. The local variable has special name resolution semantics when used in expressions. If the local variable is used in a context that expects an expression that is classified as a method group, such as an invocation expression, then the name resolves to the function rather than to the local variable. For example:

```
ReadOnly Property F(ByVal i As Integer) As Integer
    Get
        If i = 0 Then
            F = 1    ' Sets the return value.
        Else
            F = F(i – 1) ' Recursive call.
        End If
    End Get
End Property
```

The use of parentheses can cause ambiguous situations (such as `F(1)` where `F` is a property whose type is a one-dimensional array). In all ambiguous situations, the name resolves to the property rather than the local variable. For example:

```
ReadOnly Property F(ByVal i As Integer) As Integer()
    Get
        If i = 0 Then
            F = new Integer(3) { 1, 2, 3 }
        Else
            F = F(i – 1) ' Recursive call, not index.
        End If
    End Get
End Property
```

When control flow leaves the **Get** accessor body, the value of the local variable is passed back to the invocation expression. Because invoking a **Get** accessor is conceptually equivalent to reading the value of a variable, it is considered bad programming style for **Get** accessors to have observable side effects, as illustrated in the following example:

```
Class Counter
    Private Value As Integer

    Public ReadOnly Property NextValue() As Integer
        Get
            Value += 1
            Return Value
        End Get
    End Property
End Class
```

The value of the `NextValue` property depends on the number of times the property has previously been accessed. Thus, accessing the property produces an observable side effect, and the property should instead be implemented as a method.

The "no side effects" convention for **Get** accessors does not mean that **Get** accessors should always be written to simply return values stored in variables. Indeed, **Get** accessors often compute the value of a property by accessing multiple variables or invoking methods. However, a properly designed **Get** accessor performs no actions that cause observable changes in the state of the object.

```
PropertyGetDeclaration ::=
   [ Attributes ] Get LineTerminator
   [ Block ]
   End Get
```

9.7.2 Set Accessor Declarations | 9.7.3 Default Properties |9.7 Properties |
Setting and Retrieving Properties (Visual Basic Language Concepts)

9.7.2 Set Accessor Declarations

A **Set** accessor (setter) is declared by using a property set declaration. A property set declaration consists of the keyword **Set**, an optional parameter list, and a statement block. Given a property named `P`, a setter declaration implicitly declares a method with the name `set_P` with the same modifiers and parameter list as the property. If the type contains a declaration with that name, a compile-time error results.

If a parameter list is specified, it must have one member, that member must have no modifiers except **ByVal**, and its type must be the same as the type of the property. The parameter represents the property value being set. If the parameter is omitted, a parameter named **Value** is implicitly declared.

```
PropertySetDeclaration ::=
   [ Attributes ] Set [ ( ParameterList ) ] LineTerminator
   [ Block ]
   End Set
```

9.7.1 Get Accessor Declarations | 9.7.3 Default Properties | 9.7 Properties |
Setting and Retrieving Properties (Visual Basic Language Concepts)

9.7.3 Default Properties

A property that specifies the modifier **Default** is called a *default property*. Any type that allows properties may have a default property, including interfaces. The default property may be referenced without having to qualify the instance with the name of the property. Thus, given a class

```
Class Test
    Public Default ReadOnly Property Item(ByVal i As Integer) As Integer
        Get
            Return i
        End Get
    End Property
End Class
```

the code

```
Module TestModule
    Sub Main()
        Dim x As Test = New Test()
        Dim y As Integer

        y = x(10)
    End Sub
End Module
```

is equivalent to

```
Module TestModule
    Sub Main()
        Dim x As Test = New Test()
        Dim y As Integer

        y = x.Item(10)
    End Sub
End Module
```

Default properties may be overloaded, but all default properties in a type must have the same name. If a derived type declares a default property with a different name than the default property of a base type, then a warning is issued and the default property in the derived type shadows the base type default property. Similarly, if a derived type contains a non-default property that shadows a default property in a base type, the base type default property is not shadowed. For example:

```
Imports System

Class Base
    Public ReadOnly Default Property Item(ByVal i As Integer)
        Get
            Console.WriteLine("Base = " & i)
        End Get
    End Property
End Class

Class Derived
    Inherits Base

    ' This hides Item, but not the default property.
    Public Shadows ReadOnly Property Item(ByVal i As Integer)
        Get
            Console.WriteLine("Derived = " & i)
        End Get
    End Property
End Class

Class MoreDerived
```

```
    Inherits Derived

    ' This hides the default property, but not Item.
    Public Shadows ReadOnly Default Property Value(ByVal i As Integer)
        Get
            Console.WriteLine("MoreDerived = " & i)
        End Get
    End Property
End Class

Module Test
    Sub Main()
        Dim x As MoreDerived = New MoreDerived()
        Dim y As Integer
        Dim z As Derived = x

        y = x(10)   ' Calls MoreDerived.Value.
        y = x.Item(10)   ' Calls Derived.Item
        y = z(10)   ' Calls Base.Item
    End Sub
End Module
```

This program will produce the output:

```
MoreDerived = 10
Derived = 10
Base = 10
```

Because a default property with no index parameters would cause an ambiguous situation when assigning instances of the containing class, default properties must have index parameters. Furthermore, if one property overloaded on a particular name includes the **Default** modifier, all properties overloaded on that name must specify it. Default properties may not be shared or private.

10. Statements

Statements represent executable code.

A method is executed by first initializing all of its parameters to their correct values and initializing all of its local variables to the default value of their types. After parameter and local variable initialization, the method body block is executed. After the method block has been executed, execution returns to the caller of the method.

```
Statement ::=
   LocalDeclarationStatement |
   WithStatement |
   SyncLockStatement |
   EventStatement |
   AssignmentStatement |
   InvocationStatement |
   ConditionalStatement |
   LoopStatement |
   ErrorHandlingStatement |
   BranchStatement |
   ArrayHandlingStatement
StatementTerminator ::= LineTerminator | :
```

See Also

10.1 Blocks | 10.2 Local Declaration Statements | 10.3 With Statement | 10.4 SyncLock Statement | 10.5 Event Statements | 10.6 Assignment Statements | 10.7 Invocation Statements | 10.8 Conditional Statements | 10.9 Loop Statements | 10.10 Exception-Handling Statements | 10.11 Branch Statements | Statements (Visual Basic Language Reference)

10.1 Blocks

Statements are organized into blocks, which are made up of logical lines. Each logical line begins with an optional label declaration, followed by zero or more statements delimited by colons.

Labels have their own declaration space and do not interfere with other identifiers. The following example is valid and uses the name variable `x` both as a parameter and as a label.

```
Function F(ByVal x As Integer) As Integer
    If x >= 0 Then
        GoTo x
    End If
    x = -x
x:
    Return x
End Function
```

The scope of a label is the body of the method containing it.

> **Note** Because both labels and statements are delimited with colons, it is possible for a label declaration to look like a statement; label declaration always takes precedence in any ambiguous situation.

Labels may be either identifiers or integer literals.

Execution of a block begins with the first statement in the block. Once a statement has been executed, the next statement in lexical order is executed, unless a statement transfers execution elsewhere or an exception occurs.

For the sake of readability, statement productions that involve multiple substatements are treated as a single production in this specification, even though the substatements may each be by themselves on a labeled line.

```
Block ::= [ LabeledLine+ ]
LabeledLine ::= [ LabelName : ] [ Statements ] LineTerminator
LabelName ::= Identifier | IntLiteral
Statements ::=
   [ Statement ] |
   Statements : [ Statement ]
```

10.1.1 Local Variables and Parameters

A method invocation creates a copy, specific to that invocation, of the local variables and parameters of the method. A local variable or parameter comes into existence when control enters the method body that contains the local variable declaration or parameter declaration and ceases to exist when control leaves the method. All locals are initialized to their type's default value. Local variables and parameters are always publicly accessible. It is an error to refer to a local variable in a textual position that precedes its declaration, as the following example illustrates:

```
Class A
    Private i As Integer = 0

    Sub F()
        i = 1
        Dim i As Integer       ' Error, use precedes declaration.
        i = 2
    End Sub

    Sub G()
        Dim a As Integer = 1
        Dim b As Integer = a   ' This is valid.
    End Sub
End Class
```

In the `F` method above, the first assignment to `i` specifically does not refer to the field declared in the outer scope. Rather, it refers to the local variable, and it is in error because it textually precedes the declaration of the variable. In the `G` method, a subsequent variable declaration refers to a local variable declared in an earlier variable declaration within the same local variable declaration.

Each block in a method creates a declaration space for local variables. Names are introduced into this declaration space through local variable declarations in the method body and through the parameter list of the method, which introduces names into the outermost block's declaration space. Blocks do not allow shadowing of names through nesting: once a name has been declared in a block, the name may not be redeclared in any nested blocks.

Thus, in the following example, the `F` and `G` methods are in error because the name `i` is declared in the outer block and cannot be redeclared in the inner block. However, the `H` and `I` methods are valid because the two `i`'s are declared in separate non-nested blocks.

```
Class A
    Sub F()
        Dim i As Integer = 0
        If True Then
               Dim i As Integer = 1
        End If
    End Sub

    Sub G()
        If True Then
            Dim i As Integer = 0
        End If
        Dim i As Integer = 1
    End Sub

    Sub H()
        If True Then
            Dim i As Integer = 0
        End If
        If True Then
            Dim i As Integer = 1
        End If
    End Sub

    Sub I()
        Dim i As Integer
        For i = 0 To 9
            H()
        Next I
```

```
        Dim i As Integer
        For i = 0 To 9
            H()
        Next I
    End Sub
End Class
```

When the method is a function, a special local variable is implicitly declared in the method body's declaration space with the same name as the method representing the return value of the function. The local variable has special name resolution semantics when used in expressions. If the local variable is used in a context that expects an expression classified as a method group, such as an invocation expression, then the name resolves to the function rather than to the local variable. For example:

```
Function F(ByVal i As Integer) As Integer
    If i = 0 Then
        F = 1        ' Sets the return value.
    Else
        F = F(i - 1) ' Recursive call.
    End If
End Function
```

The use of parentheses can cause ambiguous situations (such as `F(1)`, where `F` is a function whose return type is a one-dimensional array); in all ambiguous situations, the name resolves to the function rather than the local variable. For example:

```
Function F(ByVal i As Integer) As Integer()
    If i = 0 Then
        F = new Integer(3) { 1, 2, 3 }
    Else
        F = F(i - 1) ' Recursive call, not an index.
    End If
End Function
```

When control flow leaves the method body, the value of the local variable is passed back to the invocation expression. If the method is a subroutine, there is no such implicit local variable, and control simply returns to the invocation expression.

If explicit local declaration is specified by the compilation environment or by **Option Explicit**, all local variables must be explicitly declared. Otherwise, local variables may be implicitly declared simply by using an undeclared simple name expression in an expression context that can accept an expression classified as a variable, with the first textual appearance of the identifier considered its "declaration." The exception to this rule is that a local variable may not be implicitly declared when it is the target of a function invocation expression, indexing expression, or a member access expression. Implicitly declared locals are always scoped to the entire method body. In the case of implicit declaration, the type of the variable is **Object** if no type character was attached to the implicit declaration; otherwise the type of the variable is the type of the type character.

10.2 Local Declaration Statements

A local declaration statement declares a new local variable, local constant, or static variable. *Local variables* and *local constants* are equivalent to instance variables and constants scoped to the method and are declared in the same way. *Static variables* are similar to **Shared** variables and are declared using the **Static** modifier.

Static variables are locals that retain their value across invocations of the method. Static variables declared within nonshared methods are per instance: each instance of the type that contains the method has its own copy of the static variable. Static variables declared within **Shared** methods are per type; there is only one copy of the static variable for all instances. While local variables are initialized to their type's default value upon each entry into the method, static variables are only initialized to their type's default value when the type or type instance is initialized. Static variables may not be declared in structures.

Local variables, local constants, and static variables always have public accessibility and may not specify accessibility modifiers. If no type is specified on a local declaration statement and strict semantics are being used, a compile-time error occurs. Otherwise the type of the property is implicitly **Object** or the type of the property's type character.

Variable initializers on local declaration statements are equivalent to assignment statements placed at the textual location of the declaration. Thus, if execution branches over the local declaration statement, the variable initializer is not executed. If the local declaration statement is executed more than once, the variable initializer is executed an equal number of times. Static variables only execute their initializer the first time. If an exception occurs while initializing a static variable, the static variable is considered initialized with the default value of the static variable's type.

The following example shows the use of initializers:

```
Imports System

Module Test
    Sub F()
        Static x As Integer = 5

        Console.WriteLine("Static variable x = " & x)
        x += 1
    End Sub

    Sub Main()
        Dim i As Integer

        For i = 1 to 3
            F()
        Next i

        i = 3
label:
        Dim y As Integer = 8

        If i > 0 Then
            Console.WriteLine("Local variable y = " & y)
            y -= 1
            i -= 1
            Goto label
        End If
    End Sub
```

This program prints:

```
Static variable x = 5
Static variable x = 6
Static variable x = 7
Local variable y = 8
Local variable y = 8
Local variable y = 8
```

Local variables, local constants, and static variables are scoped to the statement block in which they are declared. Static variables are special in that their names may only be used once throughout the entire method. For example, it is not valid to specify two

static variable declarations with the same name even if they are in different blocks.

```
LocalDeclarationStatement ::=
   LocalModifier LocalDeclarators StatementTerminator
LocalModifier ::= Static | Dim | Const
LocalDeclarators ::=
   LocalDeclarator |
   LocalDeclarators , LocalDeclarator
LocalDeclarator ::=
   LocalIdentifiers [ As TypeName ] |
   LocalIdentifier [ As [ New ] TypeName [ ( [ ArgumentList ] ) ] ]
      [ = VariableInitializer ]
LocalIdentifiers ::=
   LocalIdentifier |
   LocalIdentifiers , LocalIdentifier
LocalIdentifier ::= Identifier [ ArrayNameModifier ]
```

10.3 With Statement

A **With** statement allows multiple references to an expression's members without specifying the expression multiple times. The expression must be classified as a value and is evaluated once, upon entry into the block. Within the **With** statement block, a member access expression or dictionary access expression starting with a period or an exclamation point is evaluated as if the **With** expression preceded it. For example:

```
Structure Test
    Public x As Integer

    Function F() As Integer
        Return 10
    End Sub
End Structure

Module TestModule
    Sub Main()
        Dim y As Test

        With y
            .x = 10
            Console.WriteLine(.x)
            .x = .F()
        End With
    End Sub
End Module
```

It is invalid to branch into a **With** statement block from outside of the block.

```
WithStatement ::=
   With Expression StatementTerminator
   [ Block ]
   End With StatementTerminator
```

10.4 SyncLock Statement

A **SyncLock** statement allows statements to be synchronized on an expression, which ensures that multiple threads of execution do not execute the same statements at the same time. The expression must be classified as a value and is evaluated once, upon entry to the block. When entering the **SyncLock** block, the **Shared** method **System.Monitor.Enter** is called on the specified expression, which blocks until the thread of execution has an exclusive lock on the object returned by the expression. The type of the expression in a **SyncLock** statement must be a reference type. For example:

```
Class Test
    Private count As Integer = 0

    Public Function Add() As Integer
        SyncLock Me
            count += 1
            Add = count
        End SyncLock
    End Function

    Public Function Subtract() As Integer
        SyncLock Me
            count -= 1
            Subtract = count
        End SyncLock
    End Function
End Class
```

The example above synchronizes on the specific instance of the class `Test` to ensure that no more than one thread of execution can add or subtract from the count variable at a time for a particular instance.

The **SyncLock** block is implicitly contained by a **Try** statement whose **Finally** block calls the **Shared** method **System.Monitor.Exit** on the expression. This ensures the lock is freed even when an exception is thrown. As a result, it is invalid to branch into a **SyncLock** block from outside of the block, and a **SyncLock** block is treated as a single statement for the purposes of **Resume** and **Resume Next**. The above example is equivalent to the following code:

```
Class Test
    Private count As Integer = 0

    Public Function Add() As Integer
        Try
            System.Monitor.Enter(Me)

            count += 1
            Add = count
        Finally
            System.Monitor.Exit(Me)
        End Try
    End Function

    Public Function Subtract() As Integer
        Try
            System.Monitor.Enter(Me)

            count -= 1
            Subtract = count
        Finally
            System.Monitor.Exit(Me)
        End Try
    End Function
End Class
```

```
SyncLockStatement ::=
   SyncLock Expression StatementTerminator
   [ Block ]
```

```
    End SyncLock StatementTerminator
```

10.6 Assignment Statements | 10.7 Invocation Statements | 10.8 Conditional Statements | 10.9 Loop Statements |
10.10 Exception-Handling Statements | 10.11 Branch Statements | 10.12 Array-Handling Statements |
Event Statement (Visual Basic Language Reference)

10.5.1 RaiseEvent Statement

A **RaiseEvent** statement notifies event handlers that a particular event has occurred. The simple name expression in a **RaiseEvent** statement is interpreted as a member lookup on **Me**. Thus, `RaiseEvent x` is interpreted as if it were `RaiseEvent Me.x`. The result of the expression must be classified as an event access for an event defined in the class itself; events defined on base types cannot be used in a **RaiseEvent** statement.

The **RaiseEvent** statement is processed as a call to the **Invoke** method of the event's delegate, using the supplied parameters, if any. If there are no arguments, the parentheses may be omitted. For example:

```
Imports System

Class Raiser
    Public Event Constructed(ByVal Count As Integer)

    Public Sub New()
        Static CreationCount As Integer = 0

        CreationCount += 1
        RaiseEvent Constructed(CreationCount)
    End Sub
End Class

Module Test
    Private WithEvents x As Raiser

    Private Sub Constructed(ByVal Count As Integer) Handles x.Constructed
        Console.WriteLine("Constructed instance #" & Count)
    End Sub

    Public Sub Main()
        x = New Raiser   ' Causes "Constructed instance #1" to be printed.
        x = New Raiser   ' Causes "Constructed instance #2" to be printed.
        x = New Raiser   ' Causes "Constructed instance #3" to be printed.
    End Sub
End Module
```

The class `Raiser` above is equivalent to:

```
Class Raiser
    Public Event Constructed(ByVal Count As Integer)

    Public Sub New()
        Static CreationCount As Integer = 0

        CreationCount += 1
        ConstructedEvent.Invoke(CreationCount)
    End Sub
End Class
```

```
RaiseEventStatement ::= RaiseEvent SimpleNameExpression
   [ ( [ ArgumentList ] ) ] StatementTerminator
```

See Also

10.5.2 AddHandler and RemoveHandler Statements | 10.5 Event Statements |
RaiseEvent Statement (Visual Basic Language Reference)

10.5.2 AddHandler and RemoveHandler Statements

Although most event handlers are automatically hooked up through **WithEvents** variables, it may be necessary to dynamically add and remove event handlers at run time. **AddHandler** and **RemoveHandler** statements do this.

Each statement takes two arguments: the first argument must be an expression that is classified as an event access and the second argument must be an expression that is classified as a value. The second argument's type must be the delegate type associated with the event access. For example:

```
Imports System

Public Class Form1
    Public Sub New()
        ' Add Button1_Click as an event handler for Button1's Click event.
        AddHandler Button1.Click, AddressOf Button1_Click
    End Sub

    Private Button1 As Button = New Button()

    Sub Button1_Click(sender As Object, e As EventArgs)
        Console.WriteLine("Button1 was clicked!")
    End Sub

    Public Sub Disconnect()
        RemoveHandler Button1.Click, AddressOf Button1_Click
    End Sub
End Class
```

Given an event `E`, the statement calls the relevant `add_E` or `remove_E` method on the instance to add or remove the delegate as a handler for the event. Thus, the above code is equivalent to:

```
Imports System

Public Class Form1
    Public Sub New()
        Button1.add_Click(AddressOf Button1_Click)
    End Sub

    Private Button1 As Button = New Button()

    Sub Button1_Click(sender As Object, e As EventArgs)
        Console.WriteLine("Button1 was clicked!")
    End Sub

    Public Sub Disconnect()
        Button1.remove_Click(AddressOf Button1_Click)
    End Sub
End Class
```

```
AddHandlerStatement ::=
   AddHandler Expression , Expression StatementTerminator
RemoveHandlerStatement ::=
   RemoveHandler Expression , Expression StatementTerminator
```

10.6 Assignment Statements

An assignment statement assigns the value of an expression to a variable. There are several types of assignment.

```
AssignmentStatement ::=
   RegularAssignmentStatement |
   CompoundAssignmentStatement |
   MidAssignmentStatement
```

See Also

10.6.1 Regular Assignment Statements | 10.6.2 Compound Assignment Statements | 10.6.3 Mid Assignment Statement | 10.1 Blocks | 10.1.1 Local Variables and Parameters | 10.2 Local Declaration Statements | 10.3 With Statement | 10.4 SyncLock Statement | 10.5 Event Statements | 10.7 Invocation Statements | 10.8 Conditional Statements | 10.9 Loop Statements | 10.10 Exception-Handling Statements | 10.11 Branch Statements | 10.12 Array-Handling Statements | Assignment Operators (Visual Basic Language Reference) | Assignment Statements (Visual Basic Language Concepts)

10.6.1 Regular Assignment Statements

A simple assignment statement stores the result of an expression in a variable. The expression on the left side of the assignment operator must be classified as a variable or a property access, while the expression on the right side of the assignment operator must be classified as a value. The type of the expression must be implicitly convertible to the type of the variable or property access.

If the variable being assigned into is an array element of a reference type, a run-time check will be performed to ensure that the expression is compatible with the array-element type. In the following example, the last assignment causes a **System.ArrayTypeMismatchException** to be thrown, because an instance of `ArrayList` cannot be stored in an element of a **String** array.

```
Dim sa(10) As String
Dim oa As Object() = sa
oa(0) = Nothing ' This is allowed.
oa(1) = "Hello" ' This is allowed.
oa(2) = New ArrayList() ' ArrayTypeMismatchException is thrown.
```

If the expression on the left side of the assignment operator is classified as a variable, then the assignment statement stores the value in the variable. If the expression is classified as a property access, then the assignment statement turns the property access into an invocation of the **Set** accessor of the property with the value substituted for the value parameter. For example:

```
Module Test
    Private PValue As Integer

    Public Property P As Integer
        Get
            Return PValue
        End Get

        Set (ByVal Value As Integer)
            PValue = Value
        End Set
    End Property

    Sub Main()
        ' The following two lines are equivalent.
        P = 10
        set_P(10)
    End Sub
End Module
```

If the associated instance expression of the property access is typed as a value type but not classified as a variable, a compile-time error occurs. For example:

```
Structure S
    Public F As Integer
End Structure

Class C
    Private PValue As S

    Public Property P As S
        Get
            Return P2Value
        End Get

        Set (ByVal Value As S)
            P2Value = Value
        End Set
    End Property
End Class

Module Test
```

```
    Sub Main()
        Dim ct As C = New C()
        Dim rt As Object = new C()

        ' Compile-time error: not classified as variable.
        ct.P.F = 10

        ' Run-time exception.
        rt.P.F = 10
    End Sub
End Module
```

> **Note** The semantics of the assignment depend on the type of the variable or property to which it is being assigned. If the variable to which it is being assigned is a value type, the assignment copies the value of the expression into the variable. If the variable to which it is being assigned is a reference type, the assignment copies the reference, not the value itself, into the variable. If the type of the variable is **Object**, the assignment semantics are determined by whether the value's type is a value type or a reference type at run time.

Because the equals character (**=**) is used both for assignment and for equality, there is an ambiguity between a simple assignment and an invocation statement in situations such as `x = y.ToString()`. In all such cases, the assignment statement takes precedence over the equality operator. This means that the example expression is interpreted as `x = (y.ToString())` rather than `(x = y).ToString()`.

```
RegularAssignmentStatement ::=
   Expression = Expression StatementTerminator
```

See Also

10.6.2 Compound Assignment Statements | 10.6.3 Mid Assignment Statement | 10.6 Assignment Statements | = Operator (Visual Basic Language Reference) | Assignment Statements (Visual Basic Language Concepts)

10.6.2 Compound Assignment Statements

A *compound assignment statement* takes the form *V OP= E* (where *OP* is a valid binary operator). The expression on the left side of the assignment operator must be classified as a variable or property access, while the expression on the right side of the assignment operator must be classified as a value. The compound assignment statement is equivalent to the statement *V = V OP E* with the difference that the variable on the left side of the compound assignment operator is only evaluated once. The following example demonstrates this difference:

```
Module Test
    Function GetIndex() As Integer
        Console.WriteLine("Getting index")
        Return 1
    End Function

    Sub Main()
        Dim a(2) As Integer

        Console.WriteLine("Simple assignment")
        a(GetIndex()) = a(GetIndex()) + 1

        Console.WriteLine("Compound assignment")
        a(GetIndex()) += 1
    End Sub
End Module
```

The expression `a(GetIndex())` is evaluated twice for simple assignment but only once for compound assignment, so the code prints:

```
Simple assignment
Getting index
Getting index
Compound assignment
Getting index
```

The rule for predefined operators is simply that *V OP= E* is permitted if both *V OP E* and *V = E* are permitted. Thus, in the following example, the reason for each error is that a corresponding simple assignment would also have been an error.

```
Option Strict On
Module Test
    Private b As Byte = 0
    Private ch As Char = ControlChars.NullChar
    Private i As Integer = 0
    Sub Main()
        b += 1 ' This is allowed.
        b += 1000 ' Error; b = 1000 is not permitted.
        b += i ' Error, b = I is not permitted.
        b += CByte(i) ' This is allowed.
        ch += 1 ' Error, ch = 1 is not permitted.
        ch += ChrW(1) ' This is allowed.
    End Sub
End Module
```

```
CompoundAssignmentStatement ::=
   Expression CompoundBinaryOperator = Expression StatementTerminator
CompoundBinaryOperator ::= ^ | * | / | \ | + | - | & | < < | > >
```

See Also

10.6.1 Regular Assignment Statements | 10.6.3 Mid Assignment Statement | 10.6 Assignment Statements | Assignment Operators (Visual Basic Language Reference)

10.6.3 Mid Assignment Statement

A **Mid** assignment statement assigns a string into another string. The left side of the assignment has the same syntax as a call to the function **Microsoft.VisualBasic.Strings.Mid**. The first argument is the target of the assignment and must be classified as a variable or a property access whose type is implicitly convertible to and from **String**. The second parameter is the 1-based start position that corresponds to where the assignment should begin in the target string and must be classified as a value whose type must be implicitly convertible to **Integer**. The optional third parameter is the number of characters from the right-side value to assign into the target string and must be classified as a value whose type is implicitly convertible to **Integer**. The right side is the source string and must be classified as a value whose type is implicitly convertible to **String**. The right side is truncated to the length parameter, if specified, and replaces the characters in the left-side string, starting at the start position.

The following example displays `ab123fg`:

```
Module Test
    Sub Main()
        Dim s1 As String = "abcdefg"
        Dim s2 As String = "1234567"

        Mid$(s1, 3, 3) = s2
        Console.WriteLine(s1)
    End Sub
End Module
```

Note **Mid** is not a reserved word.

```
MidAssignmentStatement ::=
   Mid [ $ ] ( Expression , Expression [ , Expression ] ) =
      Expression StatementTerminator
```

See Also

10.6.1 Regular Assignment Statements | 10.6.2 Compound Assignment Statements | 10.6 Assignment Statements | Mid Statement (Visual Basic Language Reference) | Assignment Statements (Visual Basic Language Concepts)

10.7 Invocation Statements

An invocation statement invokes a method preceded by the optional keyword **Call**. The invocation statement is processed in the same way as the function invocation expression. The invocation expression must be classified as a value or void. Any value resulting from the evaluation of the invocation expression is discarded.

```
InvocationStatement ::= [ Call ] InvocationExpression StatementTerminator
```

10.1 Blocks | 10.1.1 Local Variables and Parameters | 10.2 Local Declaration Statements | 10.3 With Statement | 10.4 SyncLock Statement | 10.5 Event Statements | 10.6 Assignment Statements | 10.8 Conditional Statements | 10.9 Loop Statements | 10.10 Exception-Handling Statements | 10.11 Branch Statements | 10.12 Array-Handling Statements | Call Statement (Visual Basic Language Reference)

10.8 Conditional Statements

Conditional statements allow conditional execution of statements based on expressions evaluated at run time.

```
ConditionalStatement ::= IfStatement | SelectStatement
```

See Also

10.8.1 If...Then...Else Statements | 10.8.2 Select...Case Statements | 10.1 Blocks | 10.1.1 Local Variables and Parameters | 10.2 Local Declaration Statements | 10.3 With Statement | 10.4 SyncLock Statement | 10.5 Event Statements | 10.6 Assignment Statements | 10.7 Invocation Statements | 10.9 Loop Statements | 10.10 Exception-Handling Statements | 10.11 Branch Statements | 10.12 Array-Handling Statements

10.8.1 If...Then...Else Statements

An **If...Then...Else** statement is the basic conditional statement. Each expression in an **If...Then...Else** statement must be classified as a value and be implicitly convertible to **Boolean**. If the expression in the **If** statement is **True**, the statements enclosed by the **If** block are executed. If the expression is **False**, each of the **ElseIf** expressions is evaluated. If one of the **ElseIf** expressions evaluates to **True**, the corresponding block is executed. If no expression evaluates to **True** and there is an **Else** block, the **Else** block is executed. Once a block finishes executing, execution passes to the end of the **If...Then...Else** statement.

The line version of the **If** statement has a single set of statements to be executed if the **If** expression is **True** and an optional set of statements to be executed if the expression is **False**. For example:

```
Module Test
    Sub Main()
        Dim a As Integer = 10
        Dim b As Integer = 20

        ' Block If statement.
        If a < b Then
            a = b
        Else
            b = a
        End If

        ' Line If statement
        If a < b Then a = b Else b = a
    End Sub
End Module
```

```
IfStatement ::= BlockIfStatement | LineIfThenStatement
BlockIfStatement ::=
   If Expression [ Then ] StatementTerminator
   [ Block ]
   [ ElseIfStatement+ ]
   [ ElseStatement ]
   End If StatementTerminator
ElseIfStatement ::=
   ElseIf Expression [ Then ] StatementTerminator
   [ Block ]
ElseStatement ::=
   Else StatementTerminator
   [ Block ]
LineIfThenStatement ::=
   If Expression Then [Statements ] [ Else Statements ]
      StatementTerminator
```

See Also

10.8.2 Select...Case Statements | 10.8 Conditional Statements | If...Then...Else Statements (Visual Basic Language Reference) | If...Then...Else Statements (Visual Basic Language Concepts)

10.8.2 Select...Case Statements

A **Select Case** statement executes statements based on the value of an expression. The expression must be classified as a value and its type must be a primitive type or **Object**.

When a **Select Case** statement is executed, the **Select** expression is evaluated first, and the **Case** statements are then evaluated in order of textual declaration. The first **Case** statement that evaluates to **True** has its block executed. If no **Case** statement evaluates to **True** and there is a **Case Else** statement, that block is executed. Once a block has finished executing, execution passes to the end of the **Select** statement.

Execution of a **Case** block is not permitted to "fall through" to the next switch section. This prevents a common class of bugs that occur in other languages when a **Case** terminating statement is accidentally omitted. The following example illustrates this behavior:

```
Module Test
    Sub Main()
        Dim x As Integer = 10

        Select Case x
            Case 5
                Console.WriteLine("x = 5")
            Case 10
                Console.WriteLine("x = 10")
            Case 20 - 10
                Console.WriteLine("x = 20 - 10")
            Case 30
                Console.WriteLine("x = 30")
        End Select
    End Sub
End Module
```

The code prints:

```
x = 10
```

Although `Case 10` and `Case 20 - 10` select for the same value, `Case 10` is executed because it precedes `Case 20 - 10` textually. When the next **Case** is reached, execution continues after the **Select** statement.

A **Case** clause may take two forms. One form is an optional **Is** keyword, a comparison operator, and an expression. The expression is converted to the type of the **Select** expression; if the expression is not implicitly convertible to the type of the **Select** expression, a compile-time error occurs. If the **Select** expression is *E*, the comparison operator is *Op*, and the **Case** expression is *E1*, the case is evaluated as *E OP E1*. The operator must be valid for the types of the two expressions; otherwise a compile-time error occurs.

The other form is an expression optionally followed by the keyword **To** and a second expression. Both expressions are converted to the type of the **Select** expression; if either expression is not implicitly convertible to the type of the **Select** expression, a compile-time error occurs. If the **Select** expression is *E,* the first **Case** expression is *E1*, and the second **Case** expression is *E2*, the **Case** is evaluated either as *E = E1* (if no *E2* is specified) or *(E >= E1) And (E <= E2)*. The operators must be valid for the types of the two expressions; otherwise a compile-time error occurs.

```
SelectStatement ::=
   Select [ Case ] Expression StatementTerminator
   [ CaseStatement+ ]
   [ CaseElseStatement ]
   End Select StatementTerminator
CaseStatement ::=
   Case CaseClauses StatementTerminator
   [ Block ]
CaseClauses ::=

10.9.1 While...End While and Do...Loop Statements | 10.9.2 For...Next Statements |10.9.3 For Each...Next Statements | 10.1 Blocks | 10.1.1 Local Variables and Parameters | 10.2 Local Declaration Statements | 10.3 With Statement | 10.4 SyncLock Statement | 10.5 Event Statements | 10.6 Assignment Statements | 10.7 Invocation Statements | 10.8 Conditional Statements | 10.10 Exception-Handling Statements | 10.11 Branch Statements | 10.12 Array-Handling Statements | Loop Structures (Visual Basic Language Concepts)

10.9.1 While...End While and Do...Loop Statements

A **While** or **Do** loop statement loops based on a **Boolean** expression. A **While** loop statement loops as long as the **Boolean** expression evaluates to **True**; a **Do** loop statement may contain a more complex condition. In either case, the expressions must be classified as values and must be implicitly convertible to **Boolean**.

An expression may be placed after the **Do** keyword or after the **Loop** keyword, but not after both. It is also valid to specify no expression at all; in that case, the loop will never exit. If the expression is placed after **Do**, it will be evaluated before the loop block is executed on each iteration. If the expression is placed after **Loop**, it will be evaluated after the loop block has executed on each iteration. Placing the expression after **Loop** will therefore generate one more loop than placement after **Do**. The following example demonstrates this behavior:

```
Module Test
    Sub Main()
        Dim x As Integer

        x = 3
        Do While x = 1
            Console.WriteLine("First loop")
        Loop

        Do
            Console.WriteLine("Second loop")
        Loop While x = 1
    End Sub
End Module
```

The code produces the output:

```
Second Loop
Third Loop
Third Loop
```

In the case of the first loop, the condition is evaluated before the loop executes. In the case of the second loop, the condition is executed after the loop executes. The conditional expression must be prefixed with either a **While** keyword or an **Until** keyword. The former breaks the loop if the condition evaluates to **False**, the latter when the condition evaluates to **True**.

```
WhileStatement ::=
   While Expression StatementTerminator
   [ Block ]
   End While StatementTerminator
DoLoopStatement ::=
   Do [ WhileOrUntil Expression ] StatementTerminator
   [ Block ]
   Loop [ WhileOrUntil Expression ] StatementTerminator
WhileOrUntil ::= While | Until
```

10.9.2 For...Next Statements

A **For...Next** statement loops based on a set of bounds. A **For** statement specifies a loop control variable, a lower bound expression, an upper bound expression, and an optional step value expression.

The loop control variable is specified either through an identifier followed by an **As** clause or an expression. In the case of an identifier, the identifier defines a new local variable of the type specified in the **As** clause, scoped to the entire **For** loop. In the case of an expression, the expression must be classified as a variable.

The loop control variable of a **For** statement must be of a primitive numeric type (**Byte**, **Short**, **Integer**, **Long**, **Decimal**, **Single**, **Double**) or **Object**, and the bound and step expressions must be implicitly convertible to the type of the loop control. Enumerated types are treated as their underlying type, which allows use of enumerated types in **For** loops. The bounds and step expressions must be classified as values.

A loop control variable cannot be used by another enclosing **For...Next** statement. A **For** statement must be closed by a matching **Next** statement. A **Next** statement without a variable matches the innermost open **For** statement. A **Next** statement with one or more loop control variables will, from left to right, match the **For** loops that match each variable. If a variable matches a **For** loop that is not the most nested loop at that point, a compile-time error results.

At the beginning of the loop, the three expressions are evaluated in textual order and the lower bound expression is assigned to the control value. If the step value is omitted, it is implicitly the literal **1**. If the **For** loop variable is of type **Object**, at least one of the expressions at run time must be of a primitive numeric type, and all three expressions must be convertible to the widest numeric type among them. There is one exception to this rule. If the three expressions are typed as **String**, then all three expressions are converted to **Double**.

At the beginning of each loop, the control variable is compared to see if it is greater than the end point if the step expression is positive, or less than the end point if the step expression is negative. If it is, the **For** loop terminates; otherwise the loop block executes. At the **Next** statement, the step value is added to the control variable and execution returns to the top of the loop.

It is not valid to branch into a **For** loop from outside the loop.

```
ForStatement ::=
   For LoopControlVariable = Expression To Expression [ Step Expression ]
      StatementTerminator
   [ Block ]
   Next [ NextExpressionList ] StatementTerminator
LoopControlVariable ::=
   Identifier As TypeName |
   Expression
NextExpressionList ::=
   Expression |
   NextExpressionList , Expression
```

10.9.3 For Each...Next Statements

A **For Each...Next** statement loops based on the elements in an expression. A **For Each** statement specifies a loop control variable and an enumerator expression.

The loop control variable is specified either through an identifier followed by an **As** clause or an expression. In the case of an identifier, the identifier defines a new local variable of the type specified in the **As** clause, scoped to the entire **For Each** loop. In the case of an expression, the expression must be classified as a variable. The enumerator expression must be classified as a value and its type must be a collection type. An implicit conversion must exist from the element type of the collection to the type of the loop control variable.

The loop control variable cannot be used by another enclosing **For Each** statement. A **For Each** statement must be closed by a matching **Next** statement. A **Next** statement without a loop control variable matches the innermost open **For Each**. A **Next** statement with one or more loop control variables will, from left to right, match the **For Each** loops that have the same loop control variable. If a variable matches a **For Each** loop that is not the most nested loop at that point, a compile-time error occurs.

A type `C` is said to be a *collection type* if it implements the interface **System.Collections.IEnumerable** or if all of the following are true:

- `C` contains an accessible instance method with the signature `GetEnumerator()` that returns a type `E`.
- `E` contains an accessible instance method with the signature `MoveNext()` and the return type **Boolean**.
- `E` contains an accessible instance property named `Current` that has a getter. The type of this property is said to be the *element type* of the collection type.

Following is an example of a class that can be enumerated:

```
Public Class IntegerCollection
    Private integers(10) As Integer

    Public Class IntegerCollectionEnumerator
        Private collection As IntegerCollection
        Private index As Integer = -1

        Friend Sub New(ByVal c As IntegerCollection)
            collection = c
        End Sub

        Public Function MoveNext() As Boolean
            index += 1

            Return index <= 10
        End Function

        Public ReadOnly Property Current As Integer
            Get
                If index < 0 OrElse index > 10 Then
                    Throw New System.InvalidOperationException()
                End If

                Return integers(index)
            End Get
        End Property
    End Class

    Public Sub New()
        Dim i As Integer

        For i = 0 To 10
            integers(i) = I
        Next i
    End Sub

    Public Function GetEnumerator() As IntegerCollectionEnumerator
        Return New IntegerCollectionEnumerator(Me)
    End Function
```

```
End Class
```

Before the loop begins, the enumerator expression is evaluated and cast to **System.Collections.IEnumerable** if it does not satisfy the requirements above. `GetEnumerator` is called on the resulting value and the return value of the function is stored in a temporary. Then at the beginning of each loop, `MoveNext` is called on the temporary. If it returns **False**, the loop terminates. If it returns **True**, the `Current` property is retrieved, coerced to the type of the iterator variable (regardless of whether the conversion is implicit or explicit), and assigned to the iterator variable; then the loop block executes. When the **Next** statement is reached, execution returns to the top of the loop. If a variable is specified after the **Next** keyword, it must be the same as the first variable after the **For Each**. For example, consider the following code:

```
Imports System

Module Test
    Sub Main()
        Dim i As Integer
        Dim c As IntegerCollection = New IntegerCollection()

        For Each i In c
            Console.WriteLine(i)
        Next i
    End Sub
End Module
```

It is equivalent to the following code:

```
Imports System

Module Test
    Sub Main()
        Dim i As Integer
        Dim c As IntegerCollection = New IntegerCollection()

        Dim e As IntegerCollectionEnumerator

        e = c.GetEnumerator()
        While e.MoveNext()
            i = e.Current

            Console.WriteLine(i)
        End While
    End Sub
End Module
```

If the type `E` of the enumerator implements **System.IDisposable**, then the enumerator is disposed upon exiting the loop by calling the `Dispose` method. This ensures that resources held by the enumerator are released. If the method containing the **For Each** statement does not use unstructured error handling, then the **For Each** statement is wrapped in a **Try** statement with the `Dispose` method called in the **Finally** to ensure cleanup.

> **Note** The **System.Array** type is a collection type, and since all array types derive from **System.Array**, any array type expression is permitted in a **For Each** statement. For single-dimensional arrays, the **For Each** statement enumerates the array elements in increasing index order, starting with index 0 and ending with index Length - 1. For multidimensional arrays, the indices of the rightmost dimension are increased first.

For example, the following code prints `1 2 3 4`:

```
Imports System

Module Test
    Sub Main()
        Dim x(,) As Integer = { { 1, 2 }, { 3, 4 } }
        Dim i As Integer

        For Each i In x
            Console.Write(i & " ")
```

```
        Next i
    End Sub
End Module
```

It is not valid to branch into a **For Each** statement block from outside the block.

```
ForEachStatement ::=
   For Each LoopControlVariable In Expression StatementTerminator
   [ Block ]
   Next [Expression ] StatementTerminator
```

10.10 Exception-Handling Statements

Visual Basic .NET supports structured exception handling and unstructured exception handling. Only one style of exception handling may be used in a method, but the **Error** statement may be used in structured exception handling. If a method uses both styles of exception handling, a compile-time error results.

```
ErrorHandlingStatement ::=
   StructuredErrorStatement |
   UnstructuredErrorStatement
```

See Also

10.10.1 Structured Exception-Handling Statements | 10.10.2 Unstructured Exception-Handling Statements | 10.1 Blocks | 10.1.1 Local Variables and Parameters | 10.2 Local Declaration Statements | 10.3 With Statement | 10.4 SyncLock Statement | 10.5 Event Statements | 10.6 Assignment Statements | 10.7 Invocation Statements | 10.8 Conditional Statements | 10.9 Loop Statements | 10.11 Branch Statements | 10.12 Array-Handling Statements | Exception Handling (Visual Basic Language Concepts)

10.10.1 Structured Exception-Handling Statements

Structured exception handling is a method of handling errors by declaring explicit blocks within which certain exceptions will be handled. Structured exception handling is done through a **Try** statement.

For example:

```
Imports System

Module Test
    Sub ThrowException()
        Throw New Exception()
    End Sub

    Sub Main()
        Try
            ThrowException()
        Catch e As Exception
            Console.WriteLine("Caught exception!")
        Finally
            Console.WriteLine("Exiting try.")
        End Try
    End Sub
End Module
```

A **Try** statement is made up of three kinds of blocks: try blocks, catch blocks, and finally blocks. A *try block* is a statement block that contains the statements to be executed. A *catch block* is a statement block that handles an exception. A *finally block* is a statement block that contains statements to be run when the **Try** statement is exited, regardless of whether an exception has occurred and been handled. A **Try** statement, which can only contain one try block and one finally block, must contain at least one catch block or finally block. It is invalid to explicitly transfer execution into a try block except from within a catch block in the same statement.

```
StructuredErrorStatement ::=
   ThrowStatement |
   TryStatement
TryStatement ::=
   Try StatementTerminator
   [ Block ]
   [ CatchStatement+ ]
   [ FinallyStatement ]
   End Try StatementTerminator
```

See Also

10.10.1.1 Finally Blocks | 10.10.1.2 Catch Blocks | 10.10.2 Unstructured Exception-Handling Statements | 10.10 Exception-Handling Statements | Throw Statement (Visual Basic Language Reference) | Try...Catch Statements (Visual Basic Language Concepts) | Structured Exception Handling (Visual Basic Language Concepts)

10.10.1.1 Finally Blocks

A **Finally** block is always executed when execution leaves any part of the **Try** statement. No explicit action is required to execute the **Finally** block; when execution leaves the **Try** statement, the system will automatically execute the **Finally** block and then transfer execution to its intended destination. The **Finally** block is executed regardless of how execution leaves the **Try** statement: through the end of the **Try** block, through the end of a **Catch** block, through an **Exit Try** statement, through a **GoTo** statement, or by not handling a thrown exception.

It is invalid to explicitly transfer execution into a **Finally** block; it is also invalid to transfer execution out of a **Finally** block except through an exception.

```
FinallyStatement ::=
   Finally StatementTerminator
   [ Block ]
```

See Also

10.10.1.2 Catch Blocks | 10.10.1 Structured Exception-Handling Statements |
Try...Catch...Finally Statement (Visual Basic Language Reference)

10.10.1.2 Catch Blocks

If an exception occurs while processing the **Try** block, each **Catch** statement is examined in textual order to determine if it handles the exception. The identifier specified in a **Catch** clause represents the exception that has been thrown. If the identifier contains an **As** clause, then the identifier is considered to be declared within the **Catch** block's local declaration space. Otherwise, the identifier must be a local variable (not a static variable) that was defined in a containing block.

A **Catch** clause with no identifier will catch all exceptions derived from **System.Exception**. A **Catch** clause with an identifier will only catch exceptions whose types are the same as or derived from the type of the identifier. The type must be **System.Exception** or a type derived from **System.Exception**. A **Catch** clause with a **When** clause will only catch exceptions when the expression evaluates to **True**; the type of the expression must be implicitly convertible to **Boolean**. A **When** clause is only applied after checking the type of the exception, and the expression may refer to the identifier representing the exception, as this example demonstrates:

```
Imports System

Module Test
    Sub Main()
        Dim i As Integer = 5

        Try
            Throw New ArgumentException()
        Catch e As OverflowException When i = 5
            Console.WriteLine("First handler")
        Catch e As ArgumentException When i = 4
            Console.WriteLine("Second handler")
        Catch When i = 5
            Console.WriteLine("Third handler")
        End Try

    End Sub
End Module
```

This example prints:

```
Third handler
```

If a **Catch** clause handles the exception, execution transfers to the **Catch** block. At the end of the **Catch** block, execution transfers to the first statement following the **Try** statement. The **Try** statement will not handle any exceptions thrown in a **Catch** block. If no **Catch** clause handles the exception, execution transfers to a location determined by the system.

It is invalid to explicitly transfer execution into a **Catch** block.

A catch block can branch into a try block in the same **Try** statement, but only if there is no intervening nested **Try** statements. For example, the following produces a compile-time error:

```
Module Test
    Sub Main()
        Try
            Throw New Exception()
out:
        Catch e As Exception
            Try
                Throw New Exception()
            Catch eInner As Exception
                ' Error: Not directly contained.
                Goto out
            End Try
        End Try
    End Sub
End Module
```

```
CatchStatement ::=
```

```
    Catch [ Identifier As TypeName ] [ When BooleanExpression ]
       StatementTerminator
    [ Block ]
```

See Also

10.10.1.1 Finally Blocks | 10.10.1 Structured Exception-Handling Statements |
Try...Catch Statements (Visual Basic Language Concepts)

10.10.1.3 Throw Statement

The **Throw** statement raises an exception, which is represented by an instance of a type derived from **System.Exception**. If the expression is not classified as a value or is not a type derived from **System.Exception**, then a compile-time error occurs. If the expression evaluates to a null reference at run time, then a **System.NullReferenceException** exception is raised instead.

A **Throw** statement may omit the expression within a catch block of a **Try** statement. In that case, the statement rethrows the exception currently being handled within the catch block.

```
ThrowStatement ::= Throw [ Expression ] StatementTerminator
```

See Also

10.10.1.1 Finally Blocks | 10.10.1 Structured Exception-Handling Statements |
Try...Catch Statements (Visual Basic Language Concepts)

10.10.2 Unstructured Exception-Handling Statements

Unstructured exception handling is a method of handling errors by indicating statements to branch to when an exception occurs. Unstructured exception handling is implemented using three statements: the **Error** statement, the **On Error** statement, and the **Resume** statement. For example:

```
Imports System

Module Test
    Sub ThrowException()
        Error 5
    End Sub

    Sub Main()
        On Error Goto GotException

        ThrowException()
        Exit Sub

GotException:
        Console.WriteLine("Caught exception!")
        Resume Next
    End Sub
End Module
```

When a method uses unstructured exception handling, a single structured exception handler is established for the entire method that catches all exceptions. The method then keeps track of the most recent exception-handler location and the most recent exception that has been thrown. At entry to the method, the exception-handler location and the exception are both set to **Nothing**. When an exception is thrown in a method that uses unstructured exception handling, a reference to the exception object is stored in the object returned by the function **Microsoft.VisualBasic.Information.Err**.

```
UnstructuredErrorStatement ::=
   ErrorStatement |
   OnErrorStatement |
   ResumeStatement
```

See Also

10.10.2.1 Error Statement | 10.10.2.2 On Error Statement | 10.10.2.3 Resume Statement |
10.10.1 Structured Exception-Handling Statements | 10.10 Exception-Handling Statements |
Unstructured Exception Handling (Visual Basic Language Concepts)

10.10.2.1 Error Statement

An **Error** statement throws a **System.Exception** exception containing a Visual Basic 6 exception number. The expression must be classified as a value and its type must be implicitly convertible to **Integer**.

```
ErrorStatement ::= Error Expression StatementTerminator
```

See Also

10.10.2.2 On Error Statement | 10.10.2.3 Resume Statement | 10.10.2 Unstructured Exception-Handling Statements | Error Statement (Visual Basic Language Reference) | Unstructured Exception Handling (Visual Basic Language Concepts)

10.10.2.2 On Error Statement

An **On Error** statement modifies the most recent exception-handling state. It may be used in one of four ways:

- **On Error GoTo -1** resets the most recent exception to **Nothing**.
- **On Error GoTo 0** resets the most recent exception-handler location to **Nothing**.
- **On Error GoTo** *LabelName* establishes the label as the most recent exception-handler location.
- **On Error Resume Next**, establishes the **Resume Next** behavior as the most recent exception-handler location.

```
OnErrorStatement ::= On Error ErrorClause StatementTerminator
ErrorClause ::=
   GoTo - 1 |
   GoTo 0 |
   GotoStatement |
   Resume Next
```

See Also

10.10.2.1 Error Statement | 10.10.2.3 Resume Statement | 10.10.2 Unstructured Exception-Handling Statements |
On Error Statement (Visual Basic Language Reference) | Unstructured Exception Handling (Visual Basic Language Concepts)

10.10.2.3 Resume Statement

A **Resume** statement returns execution to the statement that caused the most recent exception. If the **Next** modifier is specified, execution returns to the statement that would have been executed after the statement that caused the most recent exception. If a label name is specified, execution returns to the label.

Because the **SyncLock** statement contains an implicit structured error-handling block, **Resume** and **Resume Next** have special behaviors for exceptions that occur in **SyncLock** statements. **Resume** returns execution to the beginning of the **SyncLock** statement, while **Resume Next** returns execution to the next statement following the **SyncLock** statement. For example, consider the following code:

```
Imports System

Class LockClass
End Class

Module Test
    Sub Main()
        Dim FirstTime As Boolean = False
        Dim Lock As LockClass = New LockClass()

        On Error Goto Handler

        SyncLock Lock
            Console.WriteLine("Before exception")
            FirstTime = False
            Throw New Exception()
            Console.WriteLine("After exception")
        End SyncLock

        Console.WriteLine("After SyncLock")
        Exit Sub

Handler:
        If FirstTime Then
            Resume
        Else
            Resume Next
        End If
    End Sub
End Module
```

It prints the following result.

```
Before exception
Before exception
After SyncLock
```

The first time through the **SyncLock** statement, **Resume** returns execution to the beginning of the **SyncLock** statement. The second time through the **SyncLock** statement, **Resume Next** returns execution to the end of the **SyncLock** statement. **Resume** and **Resume Next** are not allowed within a **SyncLock** statement.

In all cases, when a **Resume** statement is executed, the most recent exception is set to **Nothing**. If a **Resume** statement is executed with no most recent exception, the statement raises a **System.Exception** exception containing the Visual Basic error number `20` (Resume without error).

```
ResumeStatement ::= Resume [ ResumeClause ] StatementTerminator
ResumeClause ::= Next | LabelName
```

Resume Statement (Visual Basic Language Reference) | Unstructured Exception Handling (Visual Basic Language Concepts)

10.11 Branch Statements

Branch statements modify the flow of execution in a method. There are five branch statements:

- A **GoTo** statement causes execution to transfer to the specified label in the method.
- An **Exit** statement transfers execution to the next statement after the end of the immediately containing block statement of the specified kind. If the block is the method block, execution is transferred back to the expression that invoked the method. If the **Exit** statement is not contained within the kind of block specified in the statement, a compile-time error occurs.
- A **Stop** statement causes a debugger exception to occur.
- An **End** statement terminates the program. Finalizers are run before shutdown, but the finally blocks of any currently executing **Try** statements are not executed. This statement may not be used in programs that are not executable (for example, DLLs).
- A **Return** statement returns execution to the expression that invoked the method. If the method is a subroutine, the statement is equivalent to an **Exit Sub** statement and no expression may be supplied. If the method is a function, an expression must be supplied that is classified as a value and whose type is implicitly convertible to the return type of the function. This form is equivalent to assigning to the function return local and then executing an **Exit Function** statement.

```
BranchStatement ::=
   GotoStatement |
   ExitStatement |
   StopStatement |
   EndStatement |
   ReturnStatement
GotoStatement ::= GoTo LabelName StatementTerminator
ExitStatement ::= Exit ExitKind StatementTerminator
ExitKind ::= Do | For | While | Select | Sub | Function | Property | Try
StopStatement ::= Stop StatementTerminator
EndStatement ::= End StatementTerminator
ReturnStatement ::= Return [ Expression ]
```

10.12 Array-Handling Statements

Two statements simplify working with arrays: **ReDim** statements and **Erase** statements.

```
ArrayHandlingStatement ::=
   RedimStatement |
   EraseStatement
```

See Also

10.12.1 ReDim Statement | 10.12.2 Erase Statement | 10.1 Blocks | 10.1.1 Local Variables and Parameters | 10.2 Local Declaration Statements | 10.3 With Statement | 10.4 SyncLock Statement | 10.5 Event Statements | 10.6 Assignment Statements | 10.7 Invocation Statements | 10.8 Conditional Statements | 10.9 Loop Statements | 10.10 Exception-Handling Statements | 10.11 Branch Statements | ReDim Statement (Visual Basic Language Reference) | Erase Statement (Visual Basic Language Reference)

10.12.1 ReDim Statement

A **ReDim** statement instantiates new arrays. Each clause in the statement must be classified as a variable or a property access whose type is an array type or **Object**, and be followed by a list of array bounds. The number of the bounds must be consistent with the type of the variable; any number of bounds is allowed for **Object**. At run time, an array is instantiated for each expression from left to right with the specified bounds and then assigned to the variable or property. If the variable type is **Object**, the number of dimensions is the number of dimensions specified, and the array element type is **Object**. If the given number of dimensions is incompatible with the variable or property at run time, a **System.InvalidCastException** will be thrown. For example:

```
Module Test
    Sub Main()
        Dim o As Object
        Dim b() As Byte
        Dim i(,) As Integer

        ' The next two statements are equivalent.
        ReDim o(10,30)
        o = New Object(10, 30) {}

        ' The next two statements are equivalent.
        ReDim b(10)
        b = New Byte(10) {}

        ' The following statement throws an InvalidCastException.
        ReDim i(10, 30, 40)
    End Sub
End Module
```

If the **Preserve** keyword is specified, then the expressions must also be classifiable as a value, and the new size for each dimension except for the rightmost one must be the same as the size of the existing array. The values in the existing array are copied into the new array: if the new array is smaller, the existing values are discarded; if the new array is bigger, the extra elements will be initialized to the default value of the element type of the array. For example, consider the following code:

```
Imports System

Module Test
    Sub Main()
        Dim x(5, 5) As Integer

        x(3, 3) = 3

        ReDim Preserve x(3, 6)
        Console.WriteLine(x(3, 3) & ", " & x(3, 6))
    End Sub
End Module
```

It prints the following result:

```
3, 0
```

If the existing array reference is null at run time, no error is given. Other than the rightmost dimension, if the size of a dimension changes, a **System.ArrayTypeMismatchException** will be thrown.

```
RedimStatement ::= ReDim [ Preserve ] RedimClauses StatementTerminator
RedimClauses ::=
   RedimClause |
   RedimClauses , RedimClause
RedimClause ::= Expression ArraySizeInitializationModifier
```

See Also

10.12.2 Erase Statement

An **Erase** statement sets each of the array variables or properties specified in the statement to **Nothing**. Each expression in the statement must be classified as a variable or property access whose type is an array type or **Object**. For example:

```
Module Test
    Sub Main()
        Dim x() As Integer = New Integer(5) {}

        ' The following two statements are equivalent.
        Erase x
        x = Nothing
    End Sub
End Module
```

```
EraseStatement ::= Erase EraseExpressions StatementTerminator
EraseExpressions ::=
   Expression |
   EraseExpressions , Expression
```

11. Expressions

An expression is a sequence of operators and operands that specifies a computation of a value, or that designates a variable or constant. This chapter defines the syntax, order of evaluation of operands and operators, and meaning of expressions.

```
Expression ::=
   SimpleExpression |
   TypeExpression |
   MemberAccessExpression |
   DictionaryAccessExpression |
   IndexExpression |
   NewExpression |
   CastExpression |
   OperatorExpression
```

See Also

11.4 Simple Expressions | 11.8 Invocation Expressions | 11.6 Member Access Expressions | 11.9 Index Expressions | 11.10 New Expressions | 11.11 Cast Expressions | 11.12 Operator Expressions | 11.3 Late-Binding Expressions | 9.2.5.2 Reference Parameters | Expressions (Visual Basic Language Concepts)

11.1 Expression Classifications

Every expression is classified as one of the following:

- A value. Every value has an associated type.
- A variable. Every variable has an associated type, namely the declared type of the variable.
- A namespace. An expression with this classification can only appear as the left side of a member access. In any other context, an expression classified as a namespace causes a compile-time error.
- A type. An expression with this classification can only appear as the left side of a member access. In any other context, an expression classified as a type causes a compile-time error.
- A method group, which is a set of methods overloaded on the same name. A method group may have an associated instance expression.
- A method pointer, which represents the location of a method. A method pointer may have an associated instance expression.
- A property group, which is a set of properties overloaded on the same name. A property group may have an associated instance expression.
- A property access. Every property access has an associated type, namely the type of the property. A property access may have an associated instance expression.
- An event access. Every event access has an associated type, namely the type of the event. An event access may have an associated instance expression. An event access may appear as the first argument of the **RaiseEvent**, **AddHandler**, and **RemoveHandler** statements. In any other context, an expression classified as an event access causes a compile-time error.
- Void. This occurs when the expression is an invocation of a subroutine. An expression classified as void is only valid in the context of an invocation statement.

The final result of an expression is never a namespace, type, method group, or property group. Rather, as noted above, these categories of expressions are intermediate constructs that are only permitted in certain contexts.

Constants and Enumerations (Visual Basic Language Reference) | Constants and Enumerations (Visual Basic Language Concepts)

11.1.1 Expression Reclassification

Normally, when an expression is used in a context that requires a classification different from that of the expression, a compile-time error occurs — for example, attempting to assign a value to a literal. However, in many cases it is possible to change an expression's classification through the process of *reclassification*. The following types of expressions can be reclassified:

- A variable can be reclassified as a value. The value stored in the variable is fetched.
- A method group can be reclassified as a value. The method group expression is interpreted as an invocation expression with empty parentheses (that is, `f` is interpreted as `f()`). This reclassification may actually result in the expression being reclassified as void.
- A method pointer can be reclassified as a value. This reclassification can only occur in assignment statements or as a part of interpreting a parameter list, where the target type is known. The method pointer expression is interpreted as the argument to a delegate instantiation expression of the appropriate type. For example:

```
Delegate Sub D(ByVal i As Integer)

Module Test
    Sub F(ByVal i As Integer)

    Sub Main()
        Dim del As D

        ' The next two lines are equivalent.
        del = AddressOf F
        del = New D(AddressOf F)
    End Sub
End Module
```

- A property group can be reclassified as a property access. The property group expression is interpreted as an index expression with empty parentheses (that is, `f` is interpreted as `f()`).
- A property access can be reclassified as a value. The property access expression is interpreted as an invocation expression of the **Get** accessor of the property. If the property has no getter, then a compile-time error occurs.

A namespace expression, type expression, event access expression, or void expression cannot be reclassified. Multiple reclassifications can be done at the same time. For example:

```
Module Test
    Sub F(ByVal i As Integer)
    End Sub

    ReadOnly Property P() As Integer
        Get
        End Get
    End Sub

    Sub Main()
        F(P)
    End Sub
End Module
```

In this case, the property group expression `P` is first reclassified from a property group to a property access and then reclassified from a property access to a value. The fewest number of reclassifications are performed to reach a valid classification in the context.

4.8 Variables | 10.5 Event Statements | 11.1 Expression Classifications |
Constants and Enumerations (Visual Basic Language Reference) | Constants and Enumerations (Visual Basic Language Concepts)

11.2 Constant Expressions

A *constant expression* is an expression whose value can be fully evaluated at compile time. The type of a constant expression can be **Byte**, **Short**, **Integer**, **Long**, **Char**, **Single**, **Double**, **Decimal**, **Boolean**, **String**, or any enumeration type. The following constructs are permitted in constant expressions:

- Literals (including **Nothing**).
- References to constant type members or constant locals.
- References to members of enumeration types.
- Parenthesized subexpressions.
- Coercion expressions, provided the target type is one of the types listed above. Coercions to and from **String** are an exception to this rule and not allowed because **String** conversions are always done in the current culture of the execution environment at run time.
- The **+**, **–** and **Not** unary operators.
- The **+**, **–**, *****, **^**, **Mod**, **/**, ****, **<<**, **>>**, **&**, **And**, **Or**, **Xor**, **AndAlso**, **OrElse**, **=**, **<**, **>**, **<>**, **<=**, and **=>** binary operators, provided each operand is of a type listed above.
- The following run-time functions:
  - **Microsoft.VisualBasic.Strings.ChrW**
  - **Microsoft.VisualBasic.Strings.Chr**, if the constant value is between 0 and 128
  - **Microsoft.VisualBasic.Strings.AscW**, if the constant string is not empty
  - **Microsoft.VisualBasic.Strings.Asc**, if the constant string is not empty

Constant expressions of an integral type (**Long**, **Integer**, **Short**, **Byte**) can be implicitly converted to a narrower integral type, and constant expressions of type **Double** can be implicitly converted to **Single**, provided the value of the constant expression is within the range of the destination type. These narrowing conversions are allowed regardless of whether permissive or strict semantics are being used.

```
ConstantExpression ::= Expression
```

Constants and Enumerations (Visual Basic Language Reference) | Constants and Enumerations (Visual Basic Language Concepts)

11.3 Late-Binding Expressions

When the target of a member access expression or index expression is of type **Object**, the processing of the expression may be deferred until run time. Deferring processing this way is called *late binding*. Late binding allows **Object** variables to be used in a *typeless* way, where all resolution of members is based on the actual run-time type of the value in the variable. If strict semantics are specified by the compilation environment or by **Option Strict**, late binding causes a compile-time error. Non-public members are ignored when doing late-binding, including for the purposes of overload resolution. Note that, unlike the early-bound case, invoking or accessing a **Shared** member late bound will cause the invocation target to be evaluated at run time.

> **Note** If the expression is an invocation expression for a member defined on **System.Object**, late binding will not take place.

11.4 Simple Expressions

Simple expressions are literals, parenthesized expressions, instance expressions, or simple name expressions.

```
SimpleExpression ::=
   LiteralExpression |
   ParenthesizedExpression |
   InstanceExpression |
   SimpleNameExpression |
   AddressOfExpression
```

11.4.1 Literal Expressions | 11.4.2 Parenthesized Expressions | 11.4.3 Instance Expressions | 11.5.1 GetType Expressions | 4.8 Variables | 11.5.2 TypeOf...Is Expressions | 11.5.3 Is Expressions | 11.3 Late-Binding Expressions | 9.2.5.2 Reference Parameters | Expressions (Visual Basic Language Concepts)

11.4.1 Literal Expressions

Literal expressions evaluate to the value represented by the literal. A literal expression is classified as a value.

```
LiteralExpression ::= Literal
```

See Also

11.4.2 Parenthesized Expressions | 11.4.3 Instance Expressions | 11.5.1 GetType Expressions | 11.5.2 TypeOf...Is Expressions | 11.5.3 Is Expressions | 11. Expressions | 2.4 Literals | Expressions (Visual Basic Language Concepts)

11.4.2 Parenthesized Expressions

A parenthesized expression consists of an expression enclosed in parentheses. A parenthesized expression is classified as a value, and the enclosed expression must be classified as a value. A parenthesized expression evaluates to the value of the expression within the parentheses.

```
ParenthesizedExpression ::= ( Expression )
```

11.4.1 Literal Expressions | 11.4.3 Instance Expressions | 11.5.1 GetType Expressions | 4.8 Variables | 11.5.2 TypeOf...Is Expressions | 11.5.3 Is Expressions | 11. Expressions | Expressions (Visual Basic Language Concepts)

11.4.3 Instance Expressions

An *instance expression* is the keyword **Me**, **MyClass**, or **MyBase**. An instance expression, which may only be used within the body of a non-shared method, constructor, or property accessor, is classified as a value. Instance expressions cannot be used in the arguments to constructor invocations. The three different instance expression types are:

- The keyword **Me** represents the instance of the type containing the method or property accessor being executed.
- The keyword **MyClass** is equivalent to **Me**, but all method invocations on it are treated as if the method being invoked is non-overridable. Thus, the method called will not be affected by the run-time type of the value on which the method is being called. **MyClass** can only be used as the target expression of a member access.
- The keyword **MyBase** represents the instance of the type containing the method or property accessor being executed cast to its direct base type. All method invocations on it are treated as if the method being invoked is non-overridable. **MyBase** can only be used as the target expression of a member access. A member access using **MyBase** is called a *base access*.

The following example demonstrates how instance expressions can be used:

```
Imports System

Class Base
    Public Overridable Sub F()
        Console.WriteLine("Base.F")
    End Sub
End Class

Class Derived
    Inherits Base

    Public Overrides Sub F()
        Console.WriteLine("Derived.F")
    End Sub

    Public Sub G()
        MyClass.F()
    End Sub
End Class

Class MoreDerived
    Inherits Derived

    Public Overrides Sub F()
        Console.WriteLine("MoreDerived.F")
    End Sub

    Public Sub H()
        MyBase.F()
    End Sub
End Class

Module Test
    Sub Main()
        Dim x As MoreDerived = new MoreDerived()

        x.F()
        x.G()
        x.H()
    End Sub

End Module
```

This code prints out:

```
MoreDerived.F
Derived.F
Derived.F
```

```
InstanceExpression ::= Me | MyClass | MyBase
```

11.4.4 Simple Name Expressions

A *simple name expression* consists of a single identifier. The name is resolved and classified as follows:

- Starting with the immediately enclosing block and continuing with each enclosing outer block (if any), if the identifier matches the name of a local variable, static variable, constant local, or parameter, then the identifier refers to the matching entity. The expression is classified as a variable if it is a local variable, static variable, or parameter. The expression is classified as a value if it is a constant local with the following exception. If the local variable matched is the implicit function or **Get** accessor return local variable, and the expression is part of an invocation expression, invocation statement, or an **AddressOf** expression, then no match occurs and resolution continues.
- For each nested type containing the expression, starting from the innermost and going to the outermost, if a lookup of the identifier in the type produces a match with an accessible member:
  - If the type is the immediately enclosing type and the lookup identifies a non-shared type member, then the result is the same as a member access of the form `Me.E`, where `E` is the identifier.
  - Otherwise, the result is exactly the same as a member access of the form `T.E`, where `T` is the type containing the matching member and `E` is the identifier. In this case, it is an error for the identifier to refer to a non-shared member.
- For each nested namespace, starting from the innermost and going to the outermost namespace, do the following:
  - If the namespace contains an accessible namespace member with the given name, then the identifier refers to that member and, depending on the member, is classified as a namespace or a type.
  - Otherwise, if the namespace contains one or more accessible standard modules, and a member name lookup of the identifier produces an accessible match in exactly one standard module, then the result is exactly the same as a member access of the form `M.E`, where `M` is the standard module containing the matching member and `E` is the identifier. If the identifier matches accessible type members in more than one standard module, a compile-time error occurs.
- If the source file has one or more import aliases, and the identifier matches the name of one of them, then the identifier refers to that namespace or type.
- If the source file containing the name reference has one or more imports:
  - If the identifier matches the name of an accessible namespace or type member in exactly one import, then the identifier refers to that namespace or type. If the identifier matches the name of an accessible namespace or type members in more than one import, a compile-time error occurs.
  - Otherwise, if the imports contain one or more accessible standard modules, and a member name lookup of the identifier produces an accessible match in exactly one standard module, then the result is exactly the same as a member access of the form `M.E`, where `M` is the standard module containing the matching member and `E` is the identifier. If the identifier matches accessible type members in more than one standard module, a compile-time error occurs.
- If the compilation environment defines one or more import aliases, and the identifier matches the name of one of them, then the identifier refers to that namespace or type.
- If the compilation environment defines one or more imports:
  - If the identifier matches the name of an accessible namespace or type member in exactly one import, then the identifier refers to that namespace or type. If the identifier matches the name of accessible namespace or type members in more than one import, a compile-time error occurs.
  - Otherwise, if the imports contain one or more accessible standard modules, and a member name lookup of the identifier produces an accessible match in exactly one standard module, then the result is exactly the same as a member access of the form `M.E`, where `M` is the standard module containing the matching member and `E` is the identifier. If the identifier matches accessible type members in more than one standard module, a compile-time error occurs.
- Otherwise, the name given by the identifier is undefined and a compile-time error occurs.

```
SimpleNameExpression ::= Identifier
```

See Also

11.8 Invocation Expressions | AddressOf Operator (Visual Basic Language Reference) |
Expressions (Visual Basic Language Concepts)

11.4.5 AddressOf Expressions

An **AddressOf** expression is used to produce a method pointer. The expression consists of the **AddressOf** keyword and an expression that must be classified as a method group. The method group cannot be late-bound and it cannot refer to constructors.

The result is classified as a method pointer and the associated instance expression (if any) is the same as the associated instance expression of the method group.

```
AddressOfExpression ::= AddressOf Expression
```

See Also

6.2.3 Option Compare Statement | 11.8 Invocation Expressions | AddressOf Operator (Visual Basic Language Reference) | Delegates and the AddressOf Operator (Visual Basic Language Concepts)

11.5 Type Expressions

A *type expression* is a **GetType** expression, a **TypeOf...Is** expression, or an **Is** expression.

```
TypeExpression ::=
   GetTypeExpression |
   TypeOfIsExpression |
   IsExpression
```

See Also

11.4.1 Literal Expressions | 11.4.2 Parenthesized Expressions | 11.4.3 Instance Expressions | 11.5.1 GetType Expressions | 4.8 Variables | 11.5.2 TypeOf...Is Expressions | 11.5.3 Is Expressions | 11.3 Late-Binding Expressions | 9.2.5.2 Reference Parameters | Expressions (Visual Basic Language Concepts)

11.5.1 GetType Expressions

A **GetType** expression consists of the keyword **GetType** and the name of a type. A type expression is classified as a value, and the value of the expression is the reflection (**System.Type**) class that represents that type. The type name is allowed to be **System.Void**, the only place in the language where this type name may be referenced.

The following example demonstrates the GetType expression:

```
Imports System

Module Test
    Sub Main()
        Dim t As Type() = { GetType(Integer), GetType(System.Int32), _
            GetType(String), GetType(Double()) }
        Dim i As Integer

        For i = 0 To t.Length - 1
            Console.WriteLine(t(i).Name)
        Next i
    End Sub
End Module
```

The resulting output is:

```
Int32
Int32
String
Double()
```

```
GetTypeExpression ::= GetType ( TypeName )
```

See Also

11.4.1 Literal Expressions | 11.4.2 Parenthesized Expressions | 11.4.3 Instance Expressions | 4.8 Variables | 11.5.2 TypeOf...Is Expressions | 11.5.3 Is Expressions | 11. Expressions | GetType Operator (Visual Basic Language Reference) | Expressions (Visual Basic Language Concepts)

11.5.2 TypeOf...Is Expressions

A **TypeOf...Is** expression is used to check whether the run-time type of a value is compatible with a given type. The first operand must be classified as a value and must be of a reference type. The second operand must be a type name. The result of the expression is classified as a value and is a **Boolean** value. The expression evaluates to **True** if the run-time type of the operand is derived from or implements the type, **False** otherwise.

```
TypeOfIsExpression ::= TypeOf Expression Is TypeName
```

See Also

11.4.1 Literal Expressions | 11.4.2 Parenthesized Expressions | 11.4.3 Instance Expressions | 11.5.1 GetType Expressions | 4.8 Variables | 11.5.3 Is Expressions | 11. Expressions | TypeOf (Visual Basic Language Reference)

11.5.3 Is Expressions

An **Is** expression is used to do a reference equality comparison. Each expression must be classified as a value and the type of each expression must be a reference type. The result is classified as a value and is typed as **Boolean**. The expression evaluates to **True** if both values refer to the same instance or **False** otherwise.

```
IsExpression ::= Expression Is Expression
```

See Also

11.4.1 Literal Expressions | 11.4.2 Parenthesized Expressions | 11.4.3 Instance Expressions | 11.5.1 GetType Expressions | 4.8 Variables | 11.5.2 TypeOf...Is Expressions | 11. Expressions | Is Operator (Visual Basic Language Reference) | Expressions (Visual Basic Language Concepts)

11.6 Member Access Expressions

A member access expression is used to access a member of an entity. A member access of the form `E.I`, where `E` is an expression, a built-in type, or omitted and `I` is an identifier, is evaluated and classified as follows:

- If `E` is omitted, then the expression from the immediately containing **With** statement is substituted for `E` and the member access is performed. If there is no containing **With** statement, a compile-time error occurs.
- If `E` is classified as a namespace and `I` is the name of an accessible member of that namespace, then the result is that member. The result is classified as a namespace or a type depending on the member.
- If `E` is a built-in type or an expression classified as a type, and `I` is the name of an accessible member of `E`, then `E.I` is evaluated and classified as follows:
    - If `I` is the keyword **New**, then a compile-time error occurs.
    - If `I` identifies a type, then the result is that type.
    - If `I` identifies one or more methods, then the result is a method group with no associated instance expression.
    - If `I` identifies one or more properties, then the result is a property group with no associated instance expression.
    - If `I` identifies a shared variable, and if the variable is read-only, and the reference occurs outside the shared constructor of the type in which the variable is declared, then the result is the value of the shared variable `I` in `E`. Otherwise, the result is the shared variable `I` in `E`.
    - If `I` identifies a shared event, the result is an event access with no associated instance expression.
    - If `I` identifies a constant, then the result is the value of that constant.
    - If `I` identifies an enumeration member, then the result is the value of that enumeration member.
    - Otherwise, `E.I` is an invalid member reference, and a compile-time error occurs.
- If `E` is classified as a variable or value, the type of which is `T`, and `I` is the name of an accessible member of `E`, then `E.I` is evaluated and classified as follows:
    - If `I` is the keyword **New** and `E` is an instance expression (**Me**, **MyBase**, or **MyClass**), then the result is a method group representing the instance constructors of the type of `E` with an associated instance expression of `E`. Otherwise, a compile-time error occurs.
    - If `I` identifies one or more methods, then the result is a method group with an associated instance expression of `E`.
    - If `I` identifies one or more properties, then the result is a property group with an associated instance expression of `E`.
    - If `I` identifies a shared variable or an instance variable, and if the variable is read-only, and the reference occurs outside a constructor of the class in which the variable is declared appropriate for the kind of variable (shared or instance), then the result is the value of the variable `I` in the object referenced by `E`. If `T` is a reference type, then the result is the variable `I` in the object referenced by `E`. Otherwise, if `T` is a value type and the expression `E` is classified as a variable, the result is a variable; otherwise the result is a value.
    - If `I` identifies an event, the result is an event access with an associated instance expression of `E`.
    - If `I` identifies a constant, then the result is the value of that constant.
    - If `I` identifies an enumeration member, then the result is the value of that enumeration member.
    - If `T` is **Object**, then the result is a late-bound member lookup classified as a property group with an associated instance expression of `E`.
- Otherwise, `E.I` is an invalid member reference, and a compile-time error occurs.

If the member being accessed is shared, any expression on the left side of the period is superfluous and is not evaluated unless the member access is done late-bound. For example, consider the following code:

```
Class C
    Public Shared F As Integer = 10
End Class

Module Test
    Public Function ReturnC() As C
        Console.WriteLine("Returning a new instance of C.")
        Return New C()
    End Function

    Public Sub Main()
```

```
        Console.WriteLine("The value of F is: " & ReturnC().F)
    End Sub
End Module
```

It prints `The value of F is: 10` because the function `ReturnC` does not need to be called to provide an instance of `C` to access the shared member `F`.

A late-bound member lookup is always classified as a property group, even though at run-time the identifier may resolve to a method group. At run time, the identifier is looked up and classified as a property or a method. If late-bound member lookup fails at run time, a **System.MissingMemberException** exception is thrown. Because late-bound member lookup is done solely off the run-time type of the associated instance expression, an object's run-time type is never an interface. Therefore, it is impossible to access interface members in a late-bound member access expression.

```
MemberAccessExpression ::=
   [ [ MemberAccessBase ] . ] IdentifierOrKeyword
MemberAccessBase ::= Expression | BuiltInTypeName
```

11.7 Dictionary Member Access | 11.4 Simple Expressions | 11.8 Invocation Expressions | 11.9 Index Expressions | 11.10 New Expressions | 11.11 Cast Expressions | 11.12 Operator Expressions | 11.3 Late-Binding Expressions | 9.2.5.2 Reference Parameters

11.7 Dictionary Member Access

A *dictionary member access expression* is used to look up a member of a collection. A dictionary member access takes the form of `E!I`, where `E` is an expression that is classified as a value and `I` is an identifier. The type of the expression must have a default property indexed by a single **String** parameter. The dictionary member access expression `E!I` is transformed into the expression `E.D("I")`, where `D` is the default property of `E`. For example:

```
Class Keys
    Public ReadOnly Default Property Item(ByVal s As String) As Integer
        Get
            Return 10
        End Get
    End Property
End Class

Module Test
    Sub Main()
        Dim x As Keys = new Keys()
        Dim y As Integer
        ' The two statements are equivalent.
        y = x!abc
        y = x("abc")
    End Sub
End Module
```

If an exclamation point is specified with no expression, the expression from the immediately containing **With** statement is assumed. If there is no containing **With** statement, a compile-time error occurs.

```
DictionaryAccessExpression ::= [ Expression ] ! IdentifierOrKeyword
```

See Also

11.6 Member Access Expressions

11.8 Invocation Expressions

An invocation expression consists of an invocation target, followed by an opening parenthesis, an optional argument list, and a closing parenthesis. The target expression must be classified as a method group or a value whose type is a delegate type. If the target expression is a value, then the target of the invocation expression becomes the method group referring to the `Invoke` member of the delegate type.

An argument list has two sections: positional arguments and named arguments. *Positional arguments* are expressions and must precede any named arguments. *Named arguments* start with an identifier that can match keywords, followed by `:=` and an expression.

Given a method group, overload resolution is applied to pick a single method applicable to the given argument list. If the method group only contains one method and that method takes no arguments and is a function, then the method group is interpreted as an invocation expression with an empty argument list and the result is used as the target of an index expression. If no method is applicable, a compile-time error occurs. If the applicable method is a function, then the result of the invocation expression is classified as a value typed as the return type of the function. If the applicable method is a subroutine, then the result is classified as void.

```
InvocationExpression ::= Expression [ ( [ ArgumentList ] ) ]
ArgumentList ::=
   PositionalArgumentList , NamedArgumentList |
   PositionalArgumentList |
   NamedArgumentList
PositionalArgumentList ::=
   Expression |
   PositionalArgumentList , [ Expression ]
NamedArgumentList ::=
   IdentifierOrKeyword : = Expression |
   NamedArgumentList , IdentifierOrKeyword : = Expression
```

11.8.1 Overloaded Method Resolution

Given a method group, the applicable method in the group for an argument list is determined as follows:

- Eliminate all inaccessible members from the set.
- Eliminate all members from the set that are not applicable to the argument list. If the set is empty, a compile-time error results. If only one member remains in the set, that is the applicable member.
- Eliminate all members from the set that require narrowing coercions to be applicable to the argument list, except for the case where the argument expression type is **Object**. If the set is empty, a compile-time error results. If only one member remains in the set, that is the applicable member.
- Eliminate all remaining members from the set that require narrowing coercions to be applicable to the argument list. If the set is empty and strict semantics are not being used, the invocation target expression is reclassified as a late-bound property access and the invocation expression is reinterpreted as an index expression. If strict semantics are being used and the set is empty, a compile-time error results. If only one member remains in the set, that is the applicable member.

  > **Note** The justification for this rule is that if a program is loosely-typed (that is, most or all variables are declared as **Object**), overload resolution can be difficult because all conversions from **Object** are narrowing. Rather than have the overload resolution fail in many situations (requiring strong typing of the arguments to the method call), resolution the appropriate overloaded method to call is deferred until run time. This allows the loosely-typed call to succeed without additional casts.

- Given any two members of the set, `M` and `N`, if `M` is more applicable than `N` to the argument list, eliminate `N` from the set. If only one member remains in the set, that is the applicable member. If two or more members remain because the members are equally applicable, a compile-time error results.

A member `M` is considered *more applicable* than `N` if, for each set of parameters `Mj` and `Nj` that matches an argument `Aj`, one of the following conditions is true:

- `Mj` and `Nj` have identical types, or
- There exists a widening conversion from the type of `Mj` to the type `Nj`.

It is possible for `M` and `N` to have the same signature if one or both contains an expanded paramarray parameter. In that case, the member with the fewest number of arguments matching expanded paramarray parameters is considered more applicable.

```
Imports System

Module Test
    Sub F(ByVal ParamArray a As Object())
        Console.WriteLine("F(Object())")
    End Sub

    Sub F()
        Console.WriteLine("F()")
    End Sub

    Sub F(ByVal a As Object, ByVal b As Object)
        Console.WriteLine("F(Object, Object)")
    End Sub

    Sub F(ByVal a As Object, ByVal b As object, _
          ByVal ParamArray c As Object())
        Console.WriteLine("Object, Object, Object()")
    End Sub

    Sub Main()
        F()
        F(1)
        F(1, 2)
        F(1, 2, 3)
    End Sub
End Module
```

The above example produces the following output:

```
F()
F(Object())
F(Object, Object)
F(Object, Object, Object())
```

In the example, the first and third calls to `F` prefer `F()` and `F(Object, Object)` because they match no arguments to expanded paramarray parameters. The fourth call to `F` prefers `F(Object, Object, Object())` because two arguments match non-expanded paramarray parameters. When a class declares a method with a paramarray parameter, it is not uncommon to also include some of the expanded forms as regular methods. By doing so it is possible to avoid the allocation of an array instance that occurs when an expanded form of a method with a paramarray parameter is invoked.

> **Note** The context of the method usage is not used in overload resolution (except for determining accessibility).

Also note that because of the named parameter syntax, the ordering of the actual and formal parameters may not be the same.

See Also

11.8.2 Applicable Methods

A method is *applicable* to a set of positional arguments and named arguments if the method can be invoked using the argument list. The argument expression list is first matched against the parameter list as follows:

- First, match each positional argument in order to the list of method parameters. If there are more positional arguments than parameters and the last parameter is not a paramarray, the method is not applicable. Otherwise, the paramarray parameter is expanded with parameters of the paramarray element type to match the number of positional arguments. If a positional argument is omitted, the method is not applicable.
- Next, match each named argument to a parameter with the given name. If one of the named arguments fails to match, matches a paramarray parameter, or matches an argument already matched with another positional or named argument, the method is not applicable.
- Finally, if parameters that have not been matched are not optional, the method is not applicable. If optional parameters remain, the default value specified in the optional parameter declaration is matched to the parameter. If an **Object** parameter does not specify a default value, then the expression **System.Reflection.Missing.Value** is used. If an optional **Integer** parameter has the **Microsoft.VisualBasic.CompilerServices.OptionCompareAttribute** attribute, then the literal `1` is supplied for text comparisons and the literal `0` otherwise.

The type of each argument expression must be implicitly convertible to the type of the parameter it matches. If the parameter is a reference parameter, the argument expression must be also implicitly convertible from the type of the parameter.

If a single argument expression matches a paramarray parameter and the type of the argument expression is convertible to both the type of the paramarray parameter and the paramarray element type, the method is applicable in both its expanded and unexpanded forms, with two exceptions. If the conversion from the type of the argument expression to the paramarray type is narrowing, then the method is only applicable in its expanded form. If the argument expression is the null literal **Nothing**, then the method is only applicable in its unexpanded form. For example:

```
Imports System

Module Test
    Sub F(ParamArray a As Object())
        Dim o As Object

        For Each o In a
            Console.Write(o.GetType().FullName)
            Console.Write(" ")
        Next o
        Console.WriteLine()
    End Sub

    Sub Main()
        Dim a As Object() = { 1, "Hello", 123.456 }
        Dim o As Object = a

        F(a)
        F(CType(a, Object))
        F(o)
        F(CType(o, Object()))
    End Sub
End Module
```

The above example produces the following output:

```
System.Int32 System.String System.Double
System.Object[]
System.Object[]
System.Int32 System.String System.Double
```

In the first and last invocations of `F`, the normal form of `F` is applicable because a widening conversion exists from the argument type to the parameter type (both are of type `Object()`), and the argument is passed as a regular value parameter. In the second and third invocations, the normal form of `F` is not applicable because no widening conversion exists from the argument type to the parameter type (conversions from `Object` to `Object()` are narrowing). However, the expanded form of `F` is applicable, and a

one-element `Object()` is created by the invocation. The single element of the array is initialized with the given argument value (which itself is a reference to an `Object()`).

11.8.3 Passing Parameters

If a parameter is a value parameter, the matching argument expression must be classified as a value. The value is converted to the type of the parameter and passed in as the parameter at run time. If the parameter is a reference parameter and the matching argument expression is classified as a variable whose type is the same as the parameter, then a reference to the variable is passed in as the parameter at run time.

Otherwise, if the matching argument expression is classified as a variable, value, or property access, then a temporary variable of the type of the parameter is allocated. Before the method invocation at run time, the argument expression is reclassified as a value, converted to the type of the parameter, and assigned to the temporary variable. Then a reference to the temporary variable is passed in as the parameter. After the method invocation is evaluated, if the argument expression is classified as a variable or property access, the temporary variable is assigned to the variable expression or the property access expression. If the property access expression has no **Set** accessor, then the assignment is not performed.

11.8.4 Conditional Methods

If the target method to which an invocation expression refers is a subroutine that is not a member of an interface and if the method has one or more **System.Diagnostics.ConditionalAttribute** attributes, evaluation of the expression depends on the conditional compilation constants defined at that point in the source file. Each instance of the attribute specifies a string, which names a conditional compilation constant. Each conditional compilation constant is evaluated as if it were part of a conditional compilation statement. If the constant evaluates to **True**, the expression is evaluated normally at run time. If the constant evaluates to **False**, the expression is not evaluated at all.

When looking for the attribute, the most derived declaration of an overridable method is checked.

> **Note** The attribute is not valid on functions or interface methods and is ignored if specified on either kind of method. Thus, conditional methods will only appear in invocation statements.

11.9 Index Expressions

An *index expression* results in an array element or reclassifies a property group into a property access. An index expression consists of, in order, an expression, an opening parenthesis, an index argument list, and a closing parenthesis. The target of the index expression must be classified as either a property group or a value. An index expression is processed as follows:

- If the target expression is classified as a value and if its type is not an array type, **Object**, or **System.Array**, the type must have a default property. The index is performed on a property group that represents all of the default properties of the type (which may have different names). Although it is not valid to declare a parameterless default property in Visual Basic .NET, other languages may allow declaring such a property. Consequently, indexing a property with no arguments is allowed.
- If the expression results in a value of an array type, the number of arguments in the argument list must be the same as the rank of the array type and may not include named arguments. If any of the indexes are invalid at run time, a **System.IndexOutOfRangeException** exception is thrown. Each expression must be implicitly convertible to type **Integer**. The result of the index expression is the variable at the specified index and is classified as a variable.
- If the expression is classified as a property group, overload resolution is used to determine whether one of the properties is applicable to the index argument list. If the property group only contains one property that has a **Get** accessor and if that accessor takes no arguments, then the property group is interpreted as an index expression with an empty argument list. The result is used as the target of the current index expression. If no properties are applicable, then a compile-time error occurs. Otherwise, the expression results in a property access with the associated instance expression (if any) of the property group.
- If the expression is classified as a late-bound property group or as a value whose type is **Object** or **System.Array**, the processing of the index expression is deferred until run time and the indexing is late bound. The expression results in a late-bound property access typed as **Object**. The associated instance expression is either the target expression, if it is a value, or the associated instance expression of the property group. At run time the expression is processed as follows:
    - If the expression is classified as a late-bound property group, the expression may result in either a method group, a property group, or a value (if the member is an instance or shared variable). If the result is a method group or property group, overload resolution is applied to the group to determine the correct method for the argument list. If overload resolution fails, a **System.Reflection.AmbiguousMatchException** exception is thrown. Then the result is processed either as a property access or as an invocation and the result is returned. If the invocation is of a subroutine, the result is **Nothing**.
    - If the run-time type of the target expression is an array type or **System.Array**, the result of the index expression is the value of the variable at the specified index.
    - Otherwise, the run-time type of the expression must have a default property and the index is performed on the property group that represents all of the default properties on the type. If the type has no default property, then a **System.MissingMemberException** exception is thrown.

Because late-bound overload resolution is done on the run-time type of the arguments, it is possible that an expression might produce different results based on whether it is evaluated at compile time or run time. The following example illustrates this difference:

```
Imports System

Class Base
End Class

Class Derived
    Inherits Base
End Class

Module Test
    Sub F(ByVal b As Base)
        Console.WriteLine("F(Base)")
    End Sub

    Sub F(ByVal d As Derived)
        Console.WriteLine("F(Derived)")
    End Sub

    Sub Main()
        Dim b As Base = New Derived()
        Dim o As Object = b
```

```
        F(b)
        F(o)
    End Sub
End Module
```

This code displays:

```
F(Base)
F(Derived)
```

```
IndexExpression ::= Expression ( [ ArgumentList ] )
```

11.10 New Expressions

The **New** operator is used to create new instances of types. There are three forms of **New** expressions:

- Object-creation expressions are used to create new instances of class types and value types.
- Array-creation expressions are used to create new instances of array types.
- Delegate-creation expressions are used to create new instances of delegate types.

A **New** expression is classified as a value and the result is the new instance of the type.

```
NewExpression ::=
   ObjectCreationExpression |
   ArrayCreationExpression |
   DelegateCreationExpression
```

11.4 Simple Expressions | 11.8 Invocation Expressions | 11.6 Member Access Expressions | 11.9 Index Expressions | 11.11 Cast Expressions | 11.12 Operator Expressions | 11.3 Late-Binding Expressions | 9.2.5.2 Reference Parameters

11.10.1 Object-Creation Expressions

An object-creation expression is used to create a new instance of a class type or a structure type. The type of an object creation expression must be a class type or a structure type and cannot be a **MustInherit** class. Given an object creation expression of the form `New T(A)`, where `T` is a class type or structure type and `A` is an optional argument list, overload resolution determines the correct constructor of `T` to call. If no constructor is callable, a compile-time error occurs; otherwise the expression results in the creation of a new instance of `T` using the chosen constructor. If there are no arguments, the parentheses may be omitted.

Where an instance is allocated depends on whether the instance is a class type or a value type. **New** instances of class types are created on the system heap, while new instances of value types are created directly on the stack.

```
ObjectCreationExpression ::= New TypeName [ ( [ ArgumentList ] ) ]
```

See Also

11.10.2 Array-Creation Expressions | 11.10.3 Delegate-Creation Expressions | 11.10 New Expressions |
New (Visual Basic Language Reference) | Using the New Keyword (Visual Basic Language Concepts)

11.10.2 Array-Creation Expressions

An array-creation expression is used to create a new instance of an array type. If an array size initialization modifier is supplied, the resulting array type is derived by deleting each of the individual arguments from the array size initialization argument list. The value of each argument determines the upper bound of the corresponding dimension in the newly allocated array instance. If the array-element initializer in the expression is not empty, each argument in the argument list must be a constant, and the rank and dimension lengths specified by the expression list must match those of the array element initializer.

If an array size initialization modifier is not supplied, then the type name must be an array type and the array element initializer must be empty or the rank of the specified array type must match that of the array element initializer. The individual dimension lengths are inferred from the number of elements in each of the corresponding nesting levels of the array element initializer. If the array-element initializer is empty, the length of each dimension is zero.

An array instance's rank and length of each dimension are constant for the entire lifetime of the instance. In other words, it is not possible to change the rank of an existing array instance, nor is it possible to resize its dimensions. Elements of arrays created by array-creation expressions are always initialized to their default value.

```
ArrayCreationExpression ::=
   New TypeName [ ArraySizeInitializationModifier ]
      ArrayElementInitializer
```

See Also

11.10.1 Object-Creation Expressions | 11.10.3 Delegate-Creation Expressions | 11.10 New Expressions |
New (Visual Basic Language Reference) | Using the New Keyword (Visual Basic Language Concepts)

11.10.3 Delegate-Creation Expressions

A delegate-creation expression is used to create a new instance of a delegate type. The argument of a delegate-creation expression must be an expression classified as a method pointer.

One of the methods referenced by the method pointer must exactly match the signature of the delegate type. A method matches the delegate type if the method is not declared **MustOverride** and if both their signatures and return types match. In the following example, the `A.f` variable is initialized with a delegate that refers to the second `Square` method because that method exactly matches the signature and return type of `DoubleFunc`.

```
Delegate Function DoubleFunc(x As Double) As Double
Class A
    Private f As New DoubleFunc(AddressOf Square)
    Overloads Shared Function Square(x As Single) As Single
        Return x * x
    End Function
    Overloads Shared Function Square(x As Double) As Double
        Return x * x
    End Function
End Class
```

Had the second `Square` method not been present, a compile-time error would have occurred.

The result of the expression is a delegate instance that refers to the matching method with the associated instance expression (if any) from the method pointer expression. If the instance expression is typed as a value type, then the value type is copied onto the system heap because a delegate can only point to a method of an object on the heap. The method and object to which a delegate refers remain constant for the entire lifetime of the delegate. In other words, it is not possible to change the target or object of a delegate after it has been created.

```
DelegateCreationExpression ::= New TypeName ( Expression )
```

11.10.1 Object-Creation Expressions | 11.10.2 Array-Creation Expressions | 11.10 New Expressions |
New (Visual Basic Language Reference) | Using the New Keyword (Visual Basic Language Concepts)

11.11 Cast Expressions

A cast expression coerces an expression to a given type. Specific cast keywords coerce expressions into the primitive types. Two general cast keywords, **CType** and **DirectCast**, coerce an expression into any type.

DirectCast is different from **CType** in the way it converts expressions that are typed as **Object**. When converting an expression of type **Object** whose run-time type is a primitive value type, **DirectCast** throws a **System.InvalidCastException** exception if the specified type is not the same as the run-time type of the expression or a **System.NullReferenceException** if the expression evaluates to **Nothing**. If the specified type and the run-time type of the expression are the same, however, the run-time performance of **DirectCast** is better than that of **CType**.

If no conversion exists from the type of the expression to the specified type, a compile-time error occurs. Otherwise, the expression is classified as a value and the result is the value produced by the conversion.

```
CastExpression ::=
   DirectCast ( Expression , TypeName ) |
   CType ( Expression , TypeName ) |
   CastTarget ( Expression )
CastTarget ::=
   CBool | CByte | CChar | CDate | CDec | CDbl |
   CInt | CLng | CObj | CShort | CSng | CStr
```

11.12 Operator Expressions

There are two kinds of operators. *Unary operators* take one operand and use prefix notation (for example, `-x`). *Binary operators* take two operands and use infix notation (for example, `x + y`). With the exception of the relational operators, which always result in **Boolean**, an operator defined for a particular type results in that type. The operands to an operator must always be classified as a value; the result of an operator expression is classified as a value.

```
OperatorExpression ::=
   ArithmeticOperatorExpression |
   RelationalOperatorExpression |
   LikeOperatorExpression |
   ConcatenationOperatorExpression |
   ShortCircuitLogicalOperatorExpression |
   LogicalOperatorExpression |
   ShiftOperatorExpression
```

See Also

11.12.1 Operator Precedence and Associativity | 11.12.2 Object Operands | 11.12.3 Operator Resolution | 11.13 Arithmetic Operators | 11.14 Relational Operators | 11.15 Like Operator | 11.16 Concatenation Operator | 11.17 Logical Operators | 11.18 Shift Operators | Operators (Visual Basic Language Reference) | Operators (Visual Basic Language Concepts)

11.12.1 Operator Precedence and Associativity

When an expression contains multiple binary operators, the *precedence* of the operators controls the order in which the individual binary operators are evaluated. For example, the expression `x + y * z` is evaluated as `x + (y * z)` because the ***** operator has higher precedence than the **+** operator. The following table lists the binary operators in descending order of precedence:

Category	**Operators**
Primary	All nonoperator expressions
Exponentiation	**^**
Unary negation	**+**, **-**
Multiplicative	*****, **/**
Integer division	****
Modulus	**Mod**
Additive	**+**, **-**
Concatenation	**&**
Shift	**<<**, **>>**
Relational	**=**, **<>**, **<**, **>**, **<=**, **>=**, **Like**, **Is**, **TypeOf**...**Is**
Logical NOT	**Not**
Logical AND	**And**, **AndAlso**
Logical OR	**Or**, **OrElse**
Logical XOR	**Xor**

When an expression contains two operators with the same precedence, the *associativity* of the operators controls the order in which the operations are performed. All binary operators are left-associative, meaning that operations are performed from left to right. Precedence and associativity can be controlled using parenthetical expressions.

See Also

11.12.2 Object Operands | 11.12.3 Operator Resolution | 11.13 Arithmetic Operators | 11.14 Relational Operators | 11.15 Like Operator | 11.16 Concatenation Operator | 11.17 Logical Operators |
Operator Precedence in Visual Basic (Visual Basic Language Reference) |
Efficient Combination of Operators (Visual Basic Language Concepts)

11.12.2 Object Operands

In addition to the regular types supported by each operator, all operators support operands of type **Object**. Operators applied to **Object** operands are handled similarly to late-bound method calls made on **Object** values: the run-time type of the operands, rather than the compile-time type, determines the validity and type of the operation. If strict semantics are specified by the compilation environment or by **Option Strict**, any operators with operands of type **Object** cause a compile-time error, except for the equality (**=**), inequality (**<>**), **TypeOf...Is**, and **Is** operators.

When given one or more operands of type **Object**, the outcome of the operation is the result of applying the operator to the operand types if the run-time types of the operands are types that are supported by the operator,. The value **Nothing** is treated as the default value of the type of the other operand in a binary operator expression. In a unary operator expression, or if both operands are **Nothing** in a binary operator expression, the type of the operation is **Integer**. The result of the operation is always then cast back to **Object**. If the operand types have no valid operator, a **System.InvalidCastException** exception is thrown. Conversions at run time are done without regard to whether they are implicit or explicit.

If the result of a numeric binary operation would produce an overflow exception (regardless of whether integer overflow checking is on or off), then the result type is promoted to the next wider numeric type, if possible. For example, consider the following code:

```
Imports System

Module Test
    Sub Main()
        Dim o As Object = CObj(CByte(2)) * CObj(CByte(255))

        Console.WriteLine(o.GetType().ToString() & " = " & o)
    End Sub
End Module
```

It prints the following result:

```
Short = 512
```

If no wider numeric type is available to hold the number, a **System.OverflowException** exception is thrown.

11.12.3 Operator Resolution

Given a set of operands and an operator, the correct operator type to use is resolved as follows:

- If all operands are of the same type, and the operator is defined for the type, then no conversion occurs and the operator for that type is used.
- Any operand whose type is not defined for the operator is converted using the following steps and the operator is resolved against the new types:
    - The operand is converted to the next widest type that is defined for both the operator and the operand and to which it is implicitly convertible.
    - If there is no such type, then the operand is converted to the next narrowest type that is defined for both the operator and the operand and to which it is implicitly convertible.
    - If there is no such type or the conversion cannot occur, a compile-time error occurs.
- If one of the operands is typed as **String**, it is converted using the following rules and the operator is resolved against the new types. If **String** cannot be implicitly converted to the new type, a compile-time error occurs.
    - **Date** if the other operand is **Date**
    - **Boolean** if the other operand is **Boolean**
    - **Double** in all other cases
- Otherwise, the operands are converted to the wider of the operand types and the operator for that type is used. If the narrower operand type cannot be implicitly converted to the wider operator type, a compile-time error occurs.

For the purposes of operator resolution, the following type relationships are implicit:

- **Boolean** is the same width as **Byte**.
- **Boolean** is narrower than **Short**.
- **String** is wider than **Double**.
- **String** is wider than **Date**.
- **Char** is narrower than **String**.

Enumerated types are considered to be the same width as their underlying type.

11.13 Arithmetic Operators

The *****, **/**, ****, **^**, **Mod**, **+**, and **–** operators are the *arithmetic operators*.

Floating-point arithmetic operations may be performed with higher precision than the result type of the operation. For example, some hardware architectures support an "extended" or "long double" floating-point type with greater range and precision than the **Double** type, and implicitly perform all floating-point operations using this higher-precision type. Hardware architectures can be made to perform floating-point operations with less precision only at excessive cost in performance; rather than require an implementation to forfeit both performance and precision, Visual Basic .NET allows the higher-precision type to be used for all floating-point operations. Other than delivering more precise results, this rarely has any measurable effects. However, in expressions of the form `x * y / z`, where the multiplication produces a result that is outside the **Double** range, but the subsequent division brings the temporary result back into the **Double** range, the fact that the expression is evaluated in a higher-range format may cause a finite result to be produced instead of infinity.

```
ArithmeticOperatorExpression ::=
   UnaryPlusExpression |
   UnaryMinusExpression |
   AdditionOperatorExpression |
   SubtractionOperatorExpression |
   MultiplicationOperatorExpression |
   DivisionOperatorExpression |
   ModuloOperatorExpression |
   ExponentOperatorExpression
```

11.13.1 Unary Plus Operator

The unary plus operator is defined for the **Byte**, **Short**, **Integer**, **Long**, **Single**, **Double**, and **Decimal** types. The unary plus operator results in the value of the operand.

```
UnaryPlusExpression ::= + Expression
```

+ Operator (Visual Basic Language Reference) | Arithmetic Operators (Visual Basic Language Concepts)

11.13.2 Unary Minus Operator

The unary minus operator is defined for the following types:

- **Short**, **Integer**, and **Long**. The result is computed by subtracting the operand from zero. If integer overflow checking is on and the value of the operand is the maximum negative **Short**, **Integer**, or **Long**, a **System.OverflowException** exception is thrown. Otherwise, if the value of the operand is the maximum negative **Short**, **Integer**, or **Long**, the result is that same value, and the overflow is not reported.
- **Single** and **Double**. The result is the value of the operand with its sign inverted, including the values 0 and Infinity. If the operand is NaN, the result is also NaN.
- **Decimal**. The result is computed by subtracting the operand from zero.

```
UnaryMinusExpression ::= - Expression
```

11.13.3 Addition Operator

The addition operator computes the sum of the two operands. The addition operator is defined for the following types:

- **Byte**, **Short**, **Integer**, and **Long**. If integer overflow checking is on and the sum is outside the range of the result type, a **System.OverflowException** exception is thrown. Otherwise, overflows are not reported, and any significant high-order bits of the result are discarded.
- **Single** and **Double**. The sum is computed according to the rules of IEEE 754 arithmetic.
- **Decimal**. If the resulting value is too large to represent in the decimal format, a **System.OverflowException** exception is thrown. If the result value is too small to represent in the decimal format, the result is 0.
- **String**. The two **String** operands are concatenated together.

> **Note** When resolving the addition operator for two **Char** operands, the operands are converted to **String** values.

```
AdditionOperatorExpression ::= Expression + Expression
```

11.13.4 Subtraction Operator

The subtraction operator subtracts the second operand from the first operand. The subtraction operator is defined for the following types:

- **Byte**, **Short**, **Integer**, and **Long**. If integer overflow checking is on and the difference is outside the range of the result type, a **System.OverflowException** exception is thrown. Otherwise, overflows are not reported, and any significant high-order bits of the result are discarded.
- **Single** and **Double**. The difference is computed according to the rules of IEEE 754 arithmetic.
- **Decimal**. If the resulting value is too large to represent in the decimal format, a **System.OverflowException** exception is thrown. If the result value is too small to represent in the decimal format, the result is 0.

```
SubtractionOperatorExpression ::= Expression - Expression
```

11.13.5 Multiplication Operator

The multiplication operator computes the product of two operands. The multiplication operator is defined for the following types:

- **Byte**, **Short**, **Integer**, and **Long**. If integer overflow checking is on and the product is outside the range of the result type, a **System.OverflowException** exception is thrown. Otherwise, overflows are not reported, and any significant high-order bits of the result are discarded.
- **Single** and **Double**. The product is computed according to the rules of IEEE 754 arithmetic.
- **Decimal**. If the resulting value is too large to represent in the decimal format, a **System.OverflowException** exception is thrown. If the result value is too small to represent in the decimal format, the result is 0.

```
MultiplicationOperatorExpression ::= Expression * Expression
```

11.13.6 Division Operators

Division operators compute the quotient of two operands. There are two division operators: the regular (floating-point) division operator and the integer division operator.

The regular division operator is defined for the following types:

- **Single** and **Double**. The quotient is computed according to the rules of IEEE 754 arithmetic.
- **Decimal**. If the value of the right operand is zero, a **System.DivideByZeroException** exception is thrown. If the resulting value is too large to represent in the decimal format, a **System.OverflowException** exception is thrown. If the result value is too small to represent in the decimal format, the result is zero.

According to normal operator resolution rules, regular division purely between operands of types such as **Byte**, **Short**, **Integer**, and **Long** would cause both operands to be converted to type **Decimal**. However, when doing operator resolution on the division operator when neither type is **Decimal**, **Double** is considered narrower than **Decimal**. This convention is followed because **Double** division is more efficient than **Decimal** division.

The integer division operator is defined for **Byte**, **Short**, **Integer**, and **Long**. If the value of the right operand is zero, a **System.DivideByZeroException** exception is thrown. The division rounds the result towards zero, and the absolute value of the result is the largest possible integer that is less than the absolute value of the quotient of the two operands. The result is zero or positive when the two operands have the same sign, and zero or negative when the two operands have opposite signs. If the left operand is the maximum negative **Short**, **Integer**, or **Long**, and the right operand is –1, an overflow occurs; if integer overflow checking is on, a **System.OverflowException** exception is thrown. Otherwise, the overflow is not reported and the result is instead the value of the left operand.

```
DivisionOperatorExpression ::=
   FPDivisionOperatorExpression |
   IntegerDivisionOperatorExpression
FPDivisionOperatorExpression ::= Expression / Expression
IntegerDivisionOperatorExpression ::= Expression \ Expression
```

11.13.7 Mod Operator

The **Mod** (modulo) operator computes the remainder of the division between two operands. The **Mod** operator is defined for the following types:

- **Byte**, **Short**, **Integer** and **Long**. The result of `x Mod y` is the value produced by `x - (x \ y) * y`. If `y` is zero, a **System.DivideByZeroException** exception is thrown. The modulo operator never causes an overflow.
- **Single** and **Double**. The remainder is computed according to the rules of IEEE 754 arithmetic.
- **Decimal**. If the value of the right operand is zero, a **System.DivideByZeroException** exception is thrown. If the resulting value is too large to represent in the decimal format, a **System.OverflowException** exception is thrown. If the result value is too small to represent in the decimal format, the result is zero.

```
ModuloOperatorExpression ::= Expression Mod Expression
```

11.13.8 Exponentiation Operator

The exponentiation operator computes the first operand raised to the power of the second operand. The exponentiation operator is defined for type **Double**. The value is computed according to the rules of IEEE 754 arithmetic.

```
ExponentOperatorExpression ::= Expression ^ Expression
```

11.14 Relational Operators

The *relational operators* compare values to one other. The comparison operators are **=**, **<>**, **<**, **>**, **<=**, and **>=**. All of the relational operators result in a **Boolean** value.

The relational operators have the following general meaning:

- The **=** operator tests whether the two operands are equal.
- The **<>** operator tests whether the two operands are not equal.
- The **<** operator tests whether the first operand is less than the second operand.
- The **>** operator tests whether the first operand is greater than the second operand.
- The **<=** operator tests whether the first operand is less than or equal to the second operand.
- The **>=** operator tests whether the first operand is greater than or equal to the second operand.

The relational operators are defined for the following types:

- **Boolean**. The operators compare the truth values of the two operands. **True** is considered to be less than **False**, which matches with their numeric values.
- **Byte**, **Short**, **Integer**, and **Long**. The operators compare the numeric values of the two integral operands.
- **Single** and **Double**. The operators compare the operands according to the rules of the IEEE 754 standard.
- **Decimal**. The operators compare the numeric values of the two decimal operands.
- **Date**. The operators return the result of comparing the two date/time values.
- **Char**. The operators return the result of comparing the two Unicode values.
- **String**. The operators return the result of comparing the two values using either a binary comparison or a text comparison. The comparison used is determined by the compilation environment and the **Option Compare** statement. A binary comparison determines whether the numeric Unicode value of each character in each string is the same. A text comparison does a Unicode text comparison based on the current culture in use on the .NET Framework. When doing a string comparison, a null reference is equivalent to the string literal **""**.

```
RelationalOperatorExpression ::=
   Expression = Expression |
   Expression < > Expression |
   Expression < Expression |
   Expression > Expression |
   Expression < = Expression |
   Expression > = Expression
```

11.15 Like Operator

The **Like** operator is defined for the **String** type and determines whether a string matches a given pattern. The first operand is the string being matched, and the second operand is the pattern to match against. The pattern is made up of Unicode characters. The following character sequences have special meanings:

- The character `?` matches any single character.
- The character `*` matches zero or more characters.
- The character `#` matches any single digit (0–9).
- A list of characters surrounded by brackets (`[ab...]`) matches any single character in the list.
- A list of characters surrounded by brackets and prefixed by an exclamation point (`[!ab...]`) matches any single character not in the character list.

Two characters in a character list separated by a hyphen (`-`) specify a range of Unicode characters starting with the first character and ending with the second character. If the second character is not later in the sort order than the first character, a run-time exception occurs. A hyphen that appears at the beginning or end of a character list specifies itself.

> **Note** To match the special characters left bracket (`[`), question mark (`?`), number sign (`#`), and asterisk (`*`), brackets must enclose them. The right bracket (`]`) can not be used within a group to match itself, but it can be used outside a group as an individual character. The character sequence `[]` is considered to be the string literal `""`.

Also note that character comparisons and ordering for character lists are dependent on the type of comparisons being used. If binary comparisons are being used, character comparisons and ordering are based on the numeric Unicode values. If text comparisons are being used, character comparisons and ordering are based on the current locale being used on the .NET Framework.

In some languages, special characters in the alphabet represent two separate characters and vice versa. For example, several languages use the character æ to represent the characters `a` and `e` when they appear together, while the characters ˆ and `O` can be used to represent the character Ô. When using text comparisons, the **Like** operator recognizes such cultural equivalences. In that case, an occurrence of the single special character in either pattern or string matches the equivalent two-character sequence in the other string. Similarly, a single special character in pattern enclosed in brackets (by itself, in a list, or in a range) matches the equivalent two-character sequence in the string and vice versa.

```
LikeOperatorExpression ::= Expression Like Expression
```

11.16 Concatenation Operator

The *concatenation operator* is defined for the **String** type. To make string concatenation simpler, for the purposes of operator resolution, all conversions to **String** are considered to be widening, regardless of whether strict semantics are used. A concatenation operation results in a string that is the concatenation of the two operands in order from left to right.

In concatenation expressions, **Nothing** is treated as if it were the empty string literal **""**. Also, if only one operand is typed as **System.DBNull**, that operand is treated as if it was the literal **Nothing**.

```
ConcatenationOperatorExpression ::= Expression & Expression
```

11.17 Logical Operators

The **And**, **Not**, **Or**, and **Xor** operators, which are called the logical operators, are evaluated as follows:

- For the **Boolean** type:
  - A logical **And** operation is performed on its two operands.
  - A logical **Not** operation is performed on its operand.
  - A logical **Or** operation is performed on its two operands.
  - A logical exclusive-**Or** operation is performed on its two operands.
- For **Byte**, **Short**, **Integer**, **Long**, and all enumerated types, the specified operation is performed on each bit of the binary representation of the two operand(s):
  - **And**: The result bit is 1 if both bits are 1; otherwise the result bit is 0.
  - **Not**: The result bit is 1 if the bit is 0; otherwise the result bit is 1.
  - **Or**: The result bit is 1 if either bit is 1; otherwise the result bit is 0.
  - **Xor**: The result bit is 1 if either bit is 1 but not both bits; otherwise the result bit is 0 (that is, 1 **Xor** 0 = 1, 1 **Xor** 1 = 0).

No overflows are possible from these operations. The enumerated type operators do the bitwise operation on the underlying type of the enumerated type, but the return value is the enumerated type.

```
LogicalOperatorExpression ::=
   Not Expression |
   Expression And Expression |
   Expression Or Expression |
   Expression Xor Expression
```

11.17.1 Short-circuiting Logical Operators

The **AndAlso** and **OrElse** operators, which are the short-circuiting logical operators, are only defined for the type **Boolean**. Because of their short circuiting behavior, the second operand is not evaluated at run time if the operator result is known after evaluating the first operand.

The short-circuiting logical operators are evaluated as follows:

- If the first operand in an **AndAlso** operation evaluates to **False**, the expression returns **False**. Otherwise, the second operand is evaluated and a logical **And** operation is performed on the two results.
- If the first operand in an **OrElse** operation evaluates to **True**, the expression returns **True**. Otherwise, the second operand is evaluated and a logical **Or** operation is performed on its two results.

When evaluating the **AndAlso** or **OrElse** operators, the first operand is evaluated only once, and the second operand is either not evaluated or evaluated exactly once. For example, consider the following code:

```
Imports System

Module Test
    Function TrueValue() As Boolean
        Console.Write(" True")
        Return True
    End Function

    Function FalseValue() As Boolean
        Console.Write(" False")
        Return False
    End Function

    Sub Main()
        Console.Write("And:")
        If FalseValue() And TrueValue() Then
        End If
        Console.WriteLine()

        Console.Write("Or:")
        If TrueValue() Or FalseValue() Then
        End If
        Console.WriteLine()

        Console.Write("AndAlso:")
        If FalseValue() AndAlso TrueValue() Then
        End If
        Console.WriteLine()

        Console.WriteLine("OrElse:")
        If TrueValue() OrElse FalseValue() Then
        End If
        Console.WriteLine()
    End Sub
End Module
```

It prints the following result:

```
And: False True
Or: True False
AndAlso: False
OrElse: True
```

```
ShortCircuitLogicalOperatorExpression ::=
   Expression AndAlso Expression |
   Expression OrElse Expression
```

11.18 Shift Operators

The binary operators **<<** and **>>** perform bit shifting operations. The operators are defined for the **Byte**, **Short**, **Integer** and **Long** types. Unlike the other binary operators, the result type of a shift operation is determined as if the operator was a unary operator with just the left operand. The type of the right operand must be implicitly convertible to **Integer** and is not used in determining the result type of the operation.

The **<<** operator causes the bits in the first operand to be shifted left the number of places specified by the shift amount. The high-order bits outside the range of the result type are discarded and the low-order vacated bit positions are zero-filled.

The **>>** operator causes the bits in the first operand to be shifted right the number of places specified by the shift amount. The low-order bits are discarded and the high-order vacated bit positions are set to zero if the left operand is positive or to one if negative. If the left operand is of type **Byte**, the vacant high-order bits are zero-filled.

The shift operators shift the bits of the underlying representation of the first operand by the amount of the second operand. If the value of the second operand is greater than the number of bits in the first operand, or is negative, then the shift amount is computed as `RightOperand And SizeMask` where `SizeMask` is:

LeftOperand Type	SizeMask
Byte	7 (`&H7`)
Short	15 (`&HF`)
Integer	31 (`&H1F`)
Long	63 (`&H3F`)

If the shift amount is zero, the result of the operation is identical to the value of the first operand. No overflows are possible from these operations.

```
ShiftOperatorExpression ::=
   Expression << Expression |
   Expression >> Expression
```

   IdentifierOrKeyword : = ConstantExpression
```

6. Source Files and Namespaces

```
Start ::=
   [ OptionStatement+ ]
   [ ImportsStatement+ ]
   [ Attributes ]
   [ NamespaceMemberDeclaration+ ]
```

6.2 Compilation Options

```
OptionStatement ::=
   OptionExplicitStatement |
   OptionStrictStatement |
   OptionCompareStatement
```

6.2.1 Option Explicit Statement

```
OptionExplicitStatement ::= Option Explicit [ OnOff ] LineTerminator
OnOff ::= On | Off
```

6.2.2 Option Strict Statement

```
OptionStrictStatement ::= Option Strict [ OnOff ] LineTerminator
```

6.2.3 Option Compare Statement

```
OptionCompareStatement ::= Option Compare CompareOption LineTerminator
CompareOption ::= Binary | Text
```

6.3 Imports Statement

```
ImportsStatement ::= Imports ImportsClauses LineTerminator
ImportsClauses ::=
   ImportsClause |
   ImportsClauses , ImportsClause
ImportsClause ::= ImportsAliasClause | ImportsNamespaceClause
```

6.3.1 Import Aliases

```
ImportsAliasClause ::= Identifier = NamespaceOrTypeName
```

6.3.2 Namespace Imports

```
ImportsNamespaceClause ::= NamespaceOrTypeName
```

6.4.1 Namespace Declarations

```
NamespaceDeclaration ::=
   Namespace QualifiedIdentifier LineTerminator
   [ NamespaceMemberDeclaration+ ]
   End Namespace LineTerminator
```

6.4.2 Namespace Members

```
NamespaceMemberDeclaration ::=
   NamespaceDeclaration |
   TypeDeclaration
TypeDeclaration ::=
   ModuleDeclaration |
   NonModuleDeclaration
NonModuleDeclaration ::=
   EnumDeclaration |
   StructureDeclaration |
   InterfaceDeclaration |
   ClassDeclaration |
   DelegateDeclaration
```

7. Types

```
TypeName ::=
   NamespaceOrTypeName |
   BuiltInTypeName |
   ArrayTypeName
BuiltInTypeName ::= Object | PrimitiveTypeName
```

7.2 Interface Implementation

```
TypeImplementsClause ::= Implements Implements LineTerminator
Implements ::=
   TypeName |
   Implements , TypeName
```

7.3 Primitive Types

```
PrimitiveTypeName ::= NumericTypeName | Boolean | Date | Char | String
NumericTypeName ::= IntegralTypeName | FloatingPointTypeName | Decimal
IntegralTypeName ::= Byte | Short | Integer | Long
FloatingPointTypeName ::= Single | Double
```

7.4 Enumerations

```
EnumDeclaration ::=
   [ Attributes ] [ EnumModifier+ ] Enum Identifier
      [ As IntegralTypeName ] LineTerminator
   EnumMemberDeclaration+
   End Enum LineTerminator
EnumModifier ::= AccessModifier | Shadows
```

7.4.1 Enumeration Members

```
EnumMemberDeclaration ::=
   [ Attributes ] Identifier [ = ConstantExpression ] LineTerminator
```

7.5 Classes

```
ClassDeclaration ::=
```

```
   [ Attributes ] [ ClassModifier+ ] Class Identifier LineTerminator
   [ ClassBase ]
   [ TypeImplementsClause+ ]
   [ ClassMemberDeclaration+ ]
   End Class LineTerminator
ClassModifier ::= AccessModifier | Shadows | MustInherit | NotInheritable
```

7.5.1 Class Base Specification

```
ClassBase ::= Inherits TypeName LineTerminator
```

7.5.2 Class Members

```
ClassMemberDeclaration ::=
   NonModuleDeclaration |
   EventMemberDeclaration |
   VariableMemberDeclaration |
   ConstantMemberDeclaration |
   MethodMemberDeclaration |
   PropertyMemberDeclaration |
   ConstructorMemberDeclaration
```

7.6 Structures

```
StructureDeclaration ::=
   [ Attributes ] [ StructureModifier+ ] Structure Identifier
      LineTerminator
   [ TypeImplementsClause+ ]
   [ StructMemberDeclaration+ ]
   End Structure LineTerminator
StructureModifier ::= AccessModifier | Shadows
```

7.6.1 Structure Members

```
StructMemberDeclaration ::=
   NonModuleDeclaration |
   VariableMemberDeclaration |
   ConstantMemberDeclaration |
   EventMemberDeclaration |
   MethodMemberDeclaration |
   PropertyMemberDeclaration |
   ConstructorMemberDeclaration
```

7.7 Standard Modules

```
ModuleDeclaration ::=
   [ Attributes ] [ AccessModifier+ ] Module Identifier LineTerminator
   [ ModuleMemberDeclaration+ ]
   End Module LineTerminator
```

7.7.1 Standard Module Members

```
ModuleMemberDeclaration ::=
   NonModuleDeclaration |
   VariableMemberDeclaration |
   ConstantMemberDeclaration |
```

```
   EventMemberDeclaration |
   MethodMemberDeclaration |
   PropertyMemberDeclaration |
   ConstructorMemberDeclaration
```

7.8 Interfaces

```
InterfaceDeclaration ::=
   [ Attributes ] [ InterfaceModifier+ ] Interface Identifier
      LineTerminator
   [ InterfaceBase+ ]
   [ InterfaceMemberDeclaration+ ]
   End Interface LineTerminator
InterfaceModifier ::= AccessModifier | Shadows
```

7.8.1 Interface Inheritance

```
InterfaceBase ::= Inherits InterfaceBases LineTerminator
InterfaceBases ::=
   TypeName |
   InterfaceBases , TypeName
```

7.8.2 Interface Members

```
InterfaceMemberDeclaration ::=
   NonModuleDeclaration |
   EventMemberDeclaration |
   MethodMemberDeclaration |
   PropertyMemberDeclaration
```

7.9 Arrays

```
ArrayTypeName ::= TypeName ArrayTypeModifiers
ArrayTypeModifiers ::= ArrayTypeModifier+
ArrayTypeModifier ::= ( [ RankList ] )
RankList ::=
   , |
   RankList ,
ArrayNameModifier ::=
   ArrayTypeModifiers |
   ArraySizeInitializationModifier
```

7.10 Delegates

```
DelegateDeclaration ::=
   [ Attributes ] [ DelegateModifier+ ] Delegate MethodDeclaration
DelegateModifier ::= AccessModifier | Shadows
```

9. Type Members

9.1 Interface Method Implementation

```
ImplementsClause ::= [ Implements ImplementsList ]
ImplementsList ::=
   InterfaceMemberSpecifier |
   ImplementsList , InterfaceMemberSpecifier
```

```
InterfaceMemberSpecifier ::= TypeName . Identifier
```

9.2 Methods

```
MethodMemberDeclaration ::= MethodDeclaration | ExternalMethodDeclaration
```

9.2.1 Regular Method Declarations

```
MethodDeclaration ::= SubDeclaration | FunctionDeclaration
SubDeclaration ::=
   [ Attributes ] [ ProcedureModifier+ ] Sub Identifier
      [ ( [ ParameterList ] ) ] [ HandlesOrImplements ] LineTerminator
   [ Block ]
   [ End Sub LineTerminator ]
FunctionDeclaration ::=
   [ Attributes ] [ ProcedureModifier+ ] Function Identifier
      [ ( [ ParameterList ] ) ] [ As [ Attributes ] TypeName ]
      [ HandlesOrImplements ] LineTerminator
   [ Block ]
   [ End Function LineTerminator ]
ProcedureModifier ::=
   AccessModifier |
   Shadows |
   Shared |
   Overridable |
   NotOverridable |
   MustOverride |
   Overrides |
   Overloads
HandlesOrImplements ::= HandlesClause | ImplementsClause
```

9.2.2 External Method Declarations

```
ExternalMethodDeclaration ::=
   ExternalSubDeclaration |
   ExternalFunctionDeclaration
ExternalSubDeclaration ::=
   [ Attributes ] [ ExternalMethodModifier+ ] Declare
      [ CharsetModifier ] Sub Identifier LibraryClause
      [ AliasClause ] [ ( [ ParameterList ] ) ] LineTerminator
ExternalFunctionDeclaration ::=
   [ Attributes ] [ ExternalMethodModifier+ ] Declare
      [ CharsetModifier ] Function Identifier LibraryClause
      [ AliasClause ] [ ( [ ParameterList ] ) ]
      [ As [ Attributes ] TypeName ] LineTerminator
ExternalMethodModifier ::= AccessModifier | Shadows | Overloads
CharsetModifier ::= Ansi | Unicode | Auto
LibraryClause ::= Lib StringLiteral
AliasClause ::= Alias StringLiteral
```

9.2.5 Method Parameters

```
ParameterList ::=
   Parameter |
   ParameterList , Parameter
Parameter ::=
   [ Attributes ] ParameterModifier+ Identifier [ As TypeName ]
      [ = ConstantExpression ]
ParameterModifier ::= ByVal | ByRef | Optional | ParamArray
```

9.2.6 Event Handling

```
HandlesClause ::= [ Handles EventHandlesList ]
EventHandlesList ::=
   EventMemberSpecifier |
   EventHandlesList , EventMemberSpecifier
EventMemberSpecifier ::=
   Identifier . Identifier
   MyBase . Identifier
```

9.3 Constructors

```
ConstructorMemberDeclaration ::=
   [ Attributes ] [ ConstructorModifier+ ] Sub New
      [ ( [ ParameterList ] ) ] LineTerminator
   [ Block ]
   End Sub LineTerminator
ConstructorModifier ::= AccessModifier | Shared
```

9.4 Events

```
EventMemberDeclaration ::=
   [ Attributes ] [ EventModifiers+ ] Event Identifier ParametersOrType
      [ ImplementsClause ] LineTerminator
ParametersOrType ::=
   [ ( [ ParameterList ] ) ] |
   As TypeName
EventModifiers ::= AccessModifier | Shadows | Shared
```

9.5 Constants

```
ConstantMemberDeclaration ::=
   [ Attributes ] [ ConstantModifier+ ] Const
      ConstantDeclarators LineTerminator
ConstantModifier ::= AccessModifier | Shadows
ConstantDeclarators ::=
   ConstantDeclarator |
   ConstantDeclarators , ConstantDeclarator
ConstantDeclarator ::= Identifier [ As TypeName ] =
   ConstantExpression LineTerminator
```

9.6 Instance and Shared Variables

```
VariableMemberDeclaration ::=
   [ Attributes ] [ VariableModifier+ ] [ Dim ] VariableDeclarators
      LineTerminator
VariableModifier ::=
   AccessModifier |
   Shadows |
   Shared |
   ReadOnly |
   WithEvents
VariableDeclarators ::=
   VariableDeclarator |
   VariableDeclarators , VariableDeclarator
VariableDeclarator ::=
   VariableIdentifiers [ As TypeName ] |
   VariableIdentifier [ As [ New ] TypeName [ ( ArgumentList ) ] ]
      [ = VariableInitializer ]
```

```
VariableIdentifiers ::=
   VariableIdentifier |
   VariableIdentifiers , VariableIdentifier
VariableIdentifier ::= Identifier [ ArrayNameModifier ]
```

9.6.3 Variable Initializers

```
VariableInitializer ::= RegularInitializer | ArrayElementInitializer
```

9.6.3.1 Regular Initializers

```
RegularInitializer ::= Expression
```

9.6.3.3 Array-Size Initializers

```
ArraySizeInitializationModifier ::=
   ( UpperBoundList ) [ ArrayTypeModifiers ]
UpperBoundList::=
   Expression |
   UpperBoundList , Expression
```

9.6.3.4 Array-Element Initializers

```
ArrayElementInitializer ::= { [ VariableInitializerList ] }
VariableInitializerList ::=
   VariableInitializer |
   VariableInitializerList , VariableInitializer
VariableInitializer ::= Expression | ArrayElementInitializer
```

9.7 Properties

```
PropertyMemberDeclaration ::=
   [ Attributes ] [ PropertyModifier+ ] Property Identifier
      [ ( [ ParameterList ] ) ] [ As TypeName ] [ ImplementsClause ]
      LineTerminator
   [ PropertyAccessorDeclaration+ ]
   [ End Property LineTerminator ]
PropertyModifier ::= ProcedureModifier | Default | ReadOnly | WriteOnly
PropertyAccessorDeclaration ::=
   PropertyGetDeclaration |
   PropertySetDeclaration
```

9.7.1 Get Accessor Declarations

```
PropertyGetDeclaration ::=
   [ Attributes ] Get LineTerminator
   [ Block ]
   End Get
```

9.7.2 Set Accessor Declarations

```
PropertySetDeclaration ::=
   [ Attributes ] Set [ ( ParameterList ) ] LineTerminator
   [ Block ]
```

```
   End Set
```

10. Statements

```
Statement ::=
   LocalDeclarationStatement |
   WithStatement |
   SyncLockStatement |
   EventStatement |
   AssignmentStatement |
   InvocationStatement |
   ConditionalStatement |
   LoopStatement |
   ErrorHandlingStatement |
   BranchStatement |
   ArrayHandlingStatement
StatementTerminator ::= LineTerminator | :
```

10.1 Blocks

```
Block ::= [ LabeledLine+ ]
LabeledLine ::= [ LabelName : ] [ Statements ] LineTerminator
LabelName ::= Identifier | IntLiteral
Statements ::=
   [ Statement ] |
   Statements : [ Statement ]
```

10.2 Local Declaration Statements

```
LocalDeclarationStatement ::=
   LocalModifier LocalDeclarators StatementTerminator
LocalModifier ::= Static | Dim | Const
LocalDeclarators ::=
   LocalDeclarator |
   LocalDeclarators , LocalDeclarator
LocalDeclarator ::=
   LocalIdentifiers [ As TypeName ] |
   LocalIdentifier [ As [ New ] TypeName [ ( [ ArgumentList ] ) ] ]
      [ = VariableInitializer ]
LocalIdentifiers ::=
   LocalIdentifier |
   LocalIdentifiers , LocalIdentifier
LocalIdentifier ::= Identifier [ ArrayNameModifier ]
```

10.3 With Statement

```
WithStatement ::=
   With Expression StatementTerminator
   [ Block ]
   End With StatementTerminator
```

10.4 SyncLock Statement

```
SyncLockStatement ::=
   SyncLock Expression StatementTerminator
   [ Block ]
   End SyncLock StatementTerminator
```

10.5 Event Statements

```
EventStatement ::=
   RaiseEventStatement |
   AddHandlerStatement |
   RemoveHandlerStatement
```

10.5.1 RaiseEvent Statement

```
RaiseEventStatement ::= RaiseEvent SimpleNameExpression
   [ ( [ ArgumentList ] ) ] StatementTerminator
```

10.5.2 AddHandler and RemoveHandler Statements

```
AddHandlerStatement ::=
   AddHandler Expression , Expression StatementTerminator
RemoveHandlerStatement ::=
   RemoveHandler Expression , Expression StatementTerminator
```

10.6 Assignment Statements

```
AssignmentStatement ::=
   RegularAssignmentStatement |
   CompoundAssignmentStatement |
   MidAssignmentStatement
```

10.6.1 Regular Assignment Statements

```
RegularAssignmentStatement ::=
   Expression = Expression StatementTerminator
```

10.6.2 Compound Assignment Statements

```
CompoundAssignmentStatement ::=
   Expression CompoundBinaryOperator = Expression StatementTerminator
CompoundBinaryOperator ::= ^ | * | / | \ | + | - | & | < < | > >
```

10.6.3 Mid Assignment Statement

```
MidAssignmentStatement ::=
   Mid [ $ ] ( Expression , Expression [ , Expression ] ) =
      Expression StatementTerminator
```

10.7 Invocation Statements

```
InvocationStatement ::= [ Call ] InvocationExpression StatementTerminator
```

10.8 Conditional Statements

```
ConditionalStatement ::= IfStatement | SelectStatement
```

10.8.1 If...Then...Else Statements

```
IfStatement ::= BlockIfStatement | LineIfThenStatement
BlockIfStatement ::=
   If Expression [ Then ] StatementTerminator
   [ Block ]
   [ ElseIfStatement+ ]
   [ ElseStatement ]
   End If StatementTerminator
ElseIfStatement ::=
   ElseIf Expression [ Then ] StatementTerminator
   [ Block ]
ElseStatement ::=
   Else StatementTerminator
   [ Block ]
LineIfThenStatement ::=
   If Expression Then [Statements ] [ Else Statements ]
      StatementTerminator
```

10.8.2 Select...Case Statements

```
SelectStatement ::=
   Select [ Case ] Expression StatementTerminator
   [ CaseStatement+ ]
   [ CaseElseStatement ]
   End Select StatementTerminator
CaseStatement ::=
   Case CaseClauses StatementTerminator
   [ Block ]
CaseClauses ::=
   CaseClause |
   CaseClauses , CaseClause
CaseClause ::=
   [ Is ] ComparisonOperator Expression |
   Expression [ To Expression ]
ComparisonOperator ::= = | < > | < | > | = > | = <
CaseElseStatement ::=
   Case Else StatementTerminator
   [ Block ]
```

10.9 Loop Statements

```
LoopStatement ::=
   WhileStatement |
   DoLoopStatement |
   ForStatement |
   ForEachStatement
```

10.9.1 While...End While and Do...Loop Statements

```
WhileStatement ::=
   While Expression StatementTerminator
   [ Block ]
   End While StatementTerminator
DoLoopStatement ::=
   Do [ WhileOrUntil Expression ] StatementTerminator
   [ Block ]
   Loop [ WhileOrUntil Expression ] StatementTerminator
WhileOrUntil ::= While | Until
```

10.9.2 For...Next Statements

```
ForStatement ::=
   For LoopControlVariable = Expression To Expression [ Step Expression ]
      StatementTerminator
   [ Block ]
   Next [ NextExpressionList ] StatementTerminator
LoopControlVariable ::=
   Identifier As TypeName |
   Expression
NextExpressionList ::=
   Expression |
   NextExpressionList , Expression
```

10.9.3 For Each...Next Statements

```
ForEachStatement ::=
   For Each LoopControlVariable In Expression StatementTerminator
   [ Block ]
   Next [Expression ] StatementTerminator
```

10.10 Exception-Handling Statements

```
ErrorHandlingStatement ::=
   StructuredErrorStatement |
   UnstructuredErrorStatement
```

10.10.1 Structured Exception-Handling Statements

```
StructuredErrorStatement ::=
   ThrowStatement |
   TryStatement
TryStatement ::=
   Try StatementTerminator
   [ Block ]
   [ CatchStatement+ ]
   [ FinallyStatement ]
   End Try StatementTerminator
```

10.10.1.1 Finally Blocks

```
FinallyStatement ::=
   Finally StatementTerminator
   [ Block ]
```

10.10.1.2 Catch Blocks

```
CatchStatement ::=
   Catch [ Identifier As TypeName ] [ When BooleanExpression ]
      StatementTerminator
   [ Block ]
```

10.10.1.3 Throw Statement

```
ThrowStatement ::= Throw [ Expression ] StatementTerminator
```

10.10.2 Unstructured Exception-Handling Statements

```
UnstructuredErrorStatement ::=
   ErrorStatement |
   OnErrorStatement |
   ResumeStatement
```

10.10.2.1 Error Statement

```
ErrorStatement ::= Error Expression StatementTerminator
```

10.10.2.2 On Error Statement

```
OnErrorStatement ::= On Error ErrorClause StatementTerminator
ErrorClause ::=
   GoTo - 1 |
   GoTo 0 |
   GotoStatement |
   Resume Next
```

10.10.2.3 Resume Statement

```
ResumeStatement ::= Resume [ ResumeClause ] StatementTerminator
ResumeClause ::= Next | LabelName
```

10.11 Branch Statements

```
BranchStatement ::=
   GotoStatement |
   ExitStatement |
   StopStatement |
   EndStatement |
   ReturnStatement
GotoStatement ::= GoTo LabelName StatementTerminator
ExitStatement ::= Exit ExitKind StatementTerminator
ExitKind ::= Do | For | While | Select | Sub | Function | Property | Try
StopStatement ::= Stop StatementTerminator
EndStatement ::= End StatementTerminator
ReturnStatement ::= Return [ Expression ]
```

10.12 Array-Handling Statements

```
ArrayHandlingStatement ::=
   RedimStatement |
   EraseStatement
```

10.12.1 ReDim Statement

```
RedimStatement ::= ReDim [ Preserve ] RedimClauses StatementTerminator
RedimClauses ::=
   RedimClause |
   RedimClauses , RedimClause
RedimClause ::= Expression ArraySizeInitializationModifier
```

10.12.2 Erase Statement

```
EraseStatement ::= Erase EraseExpressions StatementTerminator
EraseExpressions ::=
   Expression |
   EraseExpressions , Expression
```

11. Expressions

```
Expression ::=
   SimpleExpression |
   TypeExpression |
   MemberAccessExpression |
   DictionaryAccessExpression |
   IndexExpression |
   NewExpression |
   CastExpression |
   OperatorExpression
```

11.2 Constant Expressions

```
ConstantExpression ::= Expression
```

11.4 Simple Expressions

```
SimpleExpression ::=
   LiteralExpression |
   ParenthesizedExpression |
   InstanceExpression |
   SimpleNameExpression |
   AddressOfExpression
```

11.4.1 Literal Expressions

```
LiteralExpression ::= Literal
```

11.4.2 Parenthesized Expressions

```
ParenthesizedExpression ::= ( Expression )
```

11.4.3 Instance Expressions

```
InstanceExpression ::= Me | MyClass | MyBase
```

11.4.4 Simple Name Expressions

```
SimpleNameExpression ::= Identifier
```

11.4.5 AddressOf Expressions

```
AddressOfExpression ::= AddressOf Expression
```

11.5 Type Expressions

```
TypeExpression ::=
   GetTypeExpression |
   TypeOfIsExpression |
   IsExpression
```

11.5.1 GetType Expressions

```
GetTypeExpression ::= GetType ( TypeName )
```

11.5.2 TypeOf...Is Expressions

```
TypeOfIsExpression ::= TypeOf Expression Is TypeName
```

11.5.3 Is Expressions

```
IsExpression ::= Expression Is Expression
```

11.6 Member Access Expressions

```
MemberAccessExpression ::=
   [ [ MemberAccessBase ] . ] IdentifierOrKeyword
MemberAccessBase ::= Expression | BuiltInTypeName
```

11.7 Dictionary Member Access

```
DictionaryAccessExpression ::= [ Expression ] ! IdentifierOrKeyword
```

11.8 Invocation Expressions

```
InvocationExpression ::= Expression [ ( [ ArgumentList ] ) ]
ArgumentList ::=
   PositionalArgumentList , NamedArgumentList |
   PositionalArgumentList |
   NamedArgumentList
PositionalArgumentList ::=
   Expression |
   PositionalArgumentList , [ Expression ]
NamedArgumentList ::=
   IdentifierOrKeyword : = Expression |
   NamedArgumentList , IdentifierOrKeyword : = Expression
```

11.9 Index Expressions

```
IndexExpression ::= Expression ( [ ArgumentList ] )
```

11.10 New Expressions

```
NewExpression ::=
   ObjectCreationExpression |
```

```
   ArrayCreationExpression |
   DelegateCreationExpression
```

11.10.1 Object-Creation Expressions

```
ObjectCreationExpression ::= New TypeName [ ( [ ArgumentList ] ) ]
```

11.10.2 Array-Creation Expressions

```
ArrayCreationExpression ::=
   New TypeName [ ArraySizeInitializationModifier ]
      ArrayElementInitializer
```

11.10.3 Delegate-Creation Expressions

```
DelegateCreationExpression ::= New TypeName ( Expression )
```

11.11 Cast Expressions

```
CastExpression ::=
   DirectCast ( Expression , TypeName ) |
   CType ( Expression , TypeName ) |
   CastTarget ( Expression )
CastTarget ::=
   CBool | CByte | CChar | CDate | CDec | CDbl |
   CInt | CLng | CObj | CShort | CSng | CStr
```

11.12 Operator Expressions

```
OperatorExpression ::=
   ArithmeticOperatorExpression |
   RelationalOperatorExpression |
   LikeOperatorExpression |
   ConcatenationOperatorExpression |
   ShortCircuitLogicalOperatorExpression |
   LogicalOperatorExpression |
   ShiftOperatorExpression
```

11.13 Arithmetic Operators

```
ArithmeticOperatorExpression ::=
   UnaryPlusExpression |
   UnaryMinusExpression |
   AdditionOperatorExpression |
   SubtractionOperatorExpression |
   MultiplicationOperatorExpression |
   DivisionOperatorExpression |
   ModuloOperatorExpression |
   ExponentOperatorExpression
```

11.13.1 Unary Plus Operator

```
UnaryPlusExpression ::= + Expression
```

11.13.2 Unary Minus Operator

```
UnaryMinusExpression ::= - Expression
```

11.13.3 Addition Operator

```
AdditionOperatorExpression ::= Expression + Expression
```

11.13.4 Subtraction Operator

```
SubtractionOperatorExpression ::= Expression - Expression
```

11.13.5 Multiplication Operator

```
MultiplicationOperatorExpression ::= Expression * Expression
```

11.13.6 Division Operators

```
DivisionOperatorExpression ::=
   FPDivisionOperatorExpression |
   IntegerDivisionOperatorExpression
FPDivisionOperatorExpression ::= Expression / Expression
IntegerDivisionOperatorExpression ::= Expression \ Expression
```

11.13.7 Mod Operator

```
ModuloOperatorExpression ::= Expression Mod Expression
```

11.13.8 Exponentiation Operator

```
ExponentOperatorExpression ::= Expression ^ Expression
```

11.14 Relational Operators

```
RelationalOperatorExpression ::=
   Expression = Expression |
   Expression < > Expression |
   Expression < Expression |
   Expression > Expression |
   Expression < = Expression |
   Expression > = Expression
```

11.15 Like Operator

```
LikeOperatorExpression ::= Expression Like Expression
```

11.16 Concatenation Operator

```
ConcatenationOperatorExpression ::= Expression & Expression
```

11.17 Logical Operators

```
LogicalOperatorExpression ::=
   Not Expression |
   Expression And Expression |
   Expression Or Expression |
   Expression Xor Expression
```

11.17.1 Short-circuiting Logical Operators

```
ShortCircuitLogicalOperatorExpression ::=
   Expression AndAlso Expression |
   Expression OrElse Expression
```

11.18 Shift Operators

```
ShiftOperatorExpression ::=
   Expression << Expression |
   Expression >> Expression
```

Visual C# Language

Microsoft C# (pronounced C sharp) is a new programming language designed for building a wide range of enterprise applications that run on the .NET Framework. An evolution of Microsoft C and Microsoft C++, C# is simple, modern, type safe, and object oriented. C# code is compiled as managed code, which means it benefits from the services of the common language runtime. These services include language interoperability, garbage collection, enhanced security, and improved versioning support.

C# is introduced as Visual C# in the Visual Studio .NET suite. Support for Visual C# includes project templates, designers, property pages, code wizards, an object model, and other features of the development environment. The library for Visual C# programming is the .NET Framework.

In This Section

C# Language Tour
: Discusses features and reasons for using C#. Includes a Documentation Map and a Comparison Between C++ and C#.

C# Compiler Options
: A reference to the C# compiler options and build errors. Includes information on Building from the Command Line.

Visual C# Code Wizards
: Wizards you can use to add files, classes, methods, properties, and other items to your projects.

C# Language Specification
: The syntax, semantics, and design of the language.

C# Programmer's Reference
: Keywords, types, operators, attributes, and preprocessor directives. Includes the C# Tutorials and topics on language features.

Related Sections

Visual Basic and Visual C#
: Designing, developing, debugging, testing, and deploying applications using Visual Basic or Visual C#.

Visual C# Samples
: Sample source code demonstrating how to program using Visual C#.

C# Language Tour

This section provides a quick tour of the C# language. It also introduces a simple C# program and examines its structure and important features.

The following topics are discussed:

- What's New in Visual C# .NET 2003
- Quick Survey of C# Features
- Why Use C#
- The C# Version of Hello World!
- General Structure of a C# Program
- Using Fully Qualified Names
- Creating and Using C# DLLs
- Comparison Between C++ and C#

For a list of entry points into the documentation, see Documentation Map.

What's New in Visual C# .NET 2003

Microsoft Visual C# .NET 2003 includes new features in the following areas:

- Compiler and Language
- Development Environment
- IntelliSense
- Code Examples

Compiler and Language

The compiler contains the following enhancements for this release:

- #line hidden is now added as an option to the **#line** directive. See C# Preprocessor Directives.
- The compiler now recognizes the `/** */` delimiters for documentation tags. See Delimiters for Documentation Tags for more information.

Development Environment

The development environment contains the following enhancements for this release:

- /nowarn is now available in the property pages of a Visual C# project. See Build, Configuration Properties for more information.
- /nostdlib is now available in the property pages of a Visual C# project. See Advanced, Configuration Properties, <Projectname> Property Pages Dialog Box for more information.
- Build events are now available for Visual C# projects. See Build Events, Common Properties, <Projectname> Property Pages Dialog Box for more information.
- The General, Common Properties property page now includes the Supported Runtimes property.

IntelliSense

IntelliSense contains the following enhancements for this release:

- Automatic hook up of events in the Code Editor. See Automatically Hooking Up to Events for more information.
- Interface implementation assistance in the Code Editor. See Implementing Interfaces for more information.
- Recognition of your most frequently used members for convenient syntax completion. See IntelliSense for Most Frequently Used Members for more information.
- Assistance with overriding base class members in the Code Editor. See IntelliSense for Override for more information.
- Accessibility from the Immediate window of the debugger. See IntelliSense in Immediate Windows for more information.

Code Examples

New code example topics have been added to Visual C# .NET documentation. The topics are designed to present concise, real-world examples of common tasks. The following example categories are shipped with this release:

- General Language Example Topics
- Graphics Programming Example Topics
- Web Applications Example Topics
- Windows Forms Example Topics

What's New in Visual Basic and Visual C#

Quick Survey of C# Features

C# is a simple but powerful programming language intended for writing enterprise applications.

The C# language is an evolution of C and C++. It uses many C++ features in the areas of statements, expressions, and operators.

C# introduces considerable improvement and innovations in areas such as type safety, versioning, events, and garbage collection.

C# provides access to the common API styles: .NET Framework, COM, Automation, and C-style APIs. It also supports unsafe mode, where you can use pointers to manipulate memory that is not under the control of the garbage collector.

C# Language Tour

Why Use C#

C# is an elegant, simple, type-safe, object-oriented language that allows enterprise programmers to build a breadth of applications.

C# also gives you the capability to build durable system-level components by virtue of the following features:

- Full COM/Platform support for existing code integration.
- Robustness through garbage collection and type safety.
- Security provided through intrinsic code trust mechanisms.
- Full support of extensible metadata concepts.

You can also interoperate with other languages, across platforms, with legacy data, by virtue of the following features:

- Full interoperability support through COM+ 1.0 and .NET Framework services with tight library-based access.
- XML support for wWeb-based component interaction.
- Versioning to provide ease of administration and deployment.

C# Language Tour

The C# Version of Hello World!

The following console program is the C# version of the traditional "Hello World!" program, which displays the string `Hello World!`.

```
// A "Hello World!" program in C#
class Hello
{
   static void Main()
   {
      System.Console.WriteLine("Hello World!");
   }
}
```

The following are important points of this program:

- Comments
- The Main Method
- Input and Output
- Compilation and Execution

Comments

The first line contains a comment:

```
// A "Hello World!" program in C#
```

The characters `//` convert the rest of the line to a comment. You can also comment a block of text by placing it between the characters `/*` and `*/`, for example:

```
/* A "Hello World!" program in C#.
This program displays the string "Hello World!" on the screen. */
```

The Main Method

The C# program must contain a `Main` method, in which control starts and ends. The `Main` method is where you create objects and execute other methods.

The `Main` method is a static method that resides inside a class or a struct. In the "Hello World!" example, it resides inside the `Hello` class. Declare the `Main` method in one of the following ways:

- It can return **void**:

  ```
  static void Main()
  {
  ...
  }
  ```

- It can also return an **int**:

  ```
  static int Main()
  {
     ...
     return 0;
  }
  ```

- With both of the return types, it can take arguments:

  ```
  static int Main(string[] args)
  {
  ```

```
    ...
    return 0;
}
```

-or-

```
static void Main(string[] args)
{
    ...
}
```

The parameter of the `Main` method is a `string` array that represents the command-line arguments used to invoke the program. Notice that, unlike C++, this array does not include the name of the executable (exe) file.

For more information on using command-line arguments, see the example in Main and Creating and Using C# DLLs.

Input and Output

C# programs generally use the input/output services provided by run-time library of the .NET Framework. The statement: `System.Console.WriteLine("Hello World!");` uses the **WriteLine** method, one of the output methods of the **Console** class in the run-time library. It displays its string parameter on the standard output stream followed by a new line. Other **Console** methods are used for different input and output operations. If you include the `using System;` statement at the beginning of the program, you can directly use the **System** classes and methods without fully qualifying them. For example:

```
Console.WriteLine("Hello World!");
```

For more information on input/output methods, see the Reference section of the .NET Framework SDK.

Compilation and Execution

You can compile the "Hello World!" program either by creating a project in the Visual Studio IDE, or by using the command line.

To compile the program from the command line:

- Create the source file using any text editor and save it using a name such as `Hello.cs`. C# source code files use the extension `.cs`.
- To invoke the compiler, enter the command:

  ```
  csc Hello.cs
  ```

  If your program does not contain any compilation errors, a `Hello.exe` file will be created.

- To run the program, enter the command:

  ```
  Hello
  ```

For more information on the C# compiler and its options, see C# Compiler Options.

C# Language Tour

General Structure of a C# Program

C# programs can consist of one or more files. Each file can contain one or more namespaces. A namespace can contain types such as classes, structs, interfaces, enumerations, and delegates, in addition to other namespaces. The following is the skeleton of a C# program that contains all of these elements.

```
// A skeleton of a C# program
using System;
namespace MyNamespace1
{
   class MyClass1
   {
   }
   struct MyStruct
   {
   }
   interface IMyInterface
   {
   }
   delegate int MyDelegate();
   enum MyEnum
   {
   }
   namespace MyNamespace2
   {
   }
   class MyClass2
   {
      public static void Main(string[] args)
      {
      }
   }
}
```

See Also

C# Language Tour

Using Fully Qualified Names

Namespaces and types have unique names, which are described by fully qualified names that indicate a logical hierarchy. For example, `A.B` is the name of the namespace or type `B` nested in the namespace or type `A`.

In the following code segment, there are nested classes and namespaces. The fully qualified name is indicated as a comment following each entity.

```
namespace N1     // N1
{
   class C1      // N1.C1
   {
      class C2   // N1.C1.C2
      {
      }
   }
   namespace N2  // N1.N2
   {
      class C2   // N1.N2.C2
      {
      }
   }
}
```

In the preceding code segment:

- The namespace `N1` is a member of the global namespace. Its fully qualified name is `N1`.
- The namespace `N2` is a member of `N1`. Its fully qualified name is `N1.N2`.
- The class `C1` is a member of the `N1`. Its fully qualified name is `N1.C1`.
- The class name `C2` is used twice in this code. However, the fully qualified names are unique. The first one is declared inside `C1`; thus its fully qualified name is: `N1.C1.C2`. The second is declared inside a namespace `N2`; thus, its fully qualified name is `N1.N2.C2`.

Using the preceding code segment, you can add a new class member `C3` to the namespace `N1.N2` as follows:

```
namespace N1.N2
{
   class C3   // N1.N2.C3
   {
   }
}
```

For more information on namespaces, see Namespaces.

C# Language Tour

Creating and Using C# DLLs

A dynamic linking library (DLL) is linked to your program at run time. To demonstrate building and using a DLL, consider the following scenario:

- `MyLibrary.DLL`: The library file that contains the methods to be called at run time. In this example, the DLL contains two methods, `Add` and `Multiply`.
- `Add.cs`: The source file that contains the method `Add(long i, long j)`. It returns the sum of its parameters. The class `AddClass` that contains the method `Add` is a member of the namespace `MyMethods`.
- `Mult.cs`: The source code that contains the method `Multiply(long x, long y)`. It returns the product of its parameters. The class `MultiplyClass` that contains the method `Multiply` is also a member of the namespace `MyMethods`.
- `MyClient.cs`: The file that contains the `Main` method. It uses the methods in the DLL file to calculate the sum and the product of the run-time arguments.

Source files

File: Add.cs

```
// Add two numbers
using System;
namespace MyMethods
{
   public class AddClass
   {
      public static long Add(long i, long j)
      {
         return(i+j);
      }
   }
}
```

File: Mult.cs

```
// Multiply two numbers
using System;
namespace MyMethods
{
   public class MultiplyClass
   {
      public static long Multiply(long x, long y)
      {
         return (x*y);
      }
   }
}
```

File: MyClient.cs

```
// Calling methods from a DLL file
using System;
using MyMethods;
class MyClient
{
   public static void Main(string[] args)
   {
      Console.WriteLine("Calling methods from MyLibrary.DLL:");
      if (args.Length != 2)
      {
         Console.WriteLine("Usage: MyClient <num1> <num2>");
```

```
            return;
        }
        long num1 = long.Parse(args[0]);
        long num2 = long.Parse(args[1]);
        long sum = AddClass.Add(num1, num2);
        long product = MultiplyClass.Multiply(num1, num2);
        Console.WriteLine("The sum of {0} and {1} is {2}",
                          num1, num2, sum);
        Console.WriteLine("The product of {0} and {1} is {2}",
                          num1, num2, product);
    }
}
```

This file contains the algorithm that uses the DLL methods, `Add` and `Multiply`. It starts with parsing the arguments entered from the command line, `num1` and `num2`. Then it calculates the sum by using the `Add` method on the `AddClass` class, and the product by using the `Multiply` method on the `MultiplyClass` class.

Notice that the **using** directive at the beginning of the file allows you to use the unqualified class names to reference the DLL methods at compile time, for example:

```
MultiplyClass.Multiply(num1, num2);
```

Otherwise, you have to use the fully qualified names, for example:

```
MyMethods.MultiplyClass.Multiply(num1, num2);
```

Compilation

To build the file `MyLibrary.DLL`, compile the two files `Add.cs` and `Mult.cs` using the following command line:

```
csc /target:library /out:MyLibrary.DLL Add.cs Mult.cs
```

The /target:library compiler option tells the compiler to output a DLL instead of an EXE file. The /out compiler option followed by a file name is used to specify the DLL file name. Otherwise, the compiler uses the first file (`Add.cs`) as the name of the DLL.

To build the executable file, `MyClient.exe`, use the following command line:

```
csc /out:MyClient.exe /reference:MyLibrary.DLL MyClient.cs
```

The `/out` compiler option tells the compiler to output an EXE file and specifies the name of the output file (`MyClient.exe`). This compiler option is optional. The /reference compiler option specifies the DLL file(s) that this program uses.

Execution

To run the program, enter the name of the EXE file, followed by two numbers, for example:

```
MyClient 1234 5678
```

Output

```
Calling methods from MyLibrary.DLL:
The sum of 1234 and 5678 is 6912
The product of 1234 and 5678 is 7006652
```

Comparison Between C++ and C#

The following table contains important comparisons between C++ and C# features. If you are a C++ programmer, this table will give you the most important differences between the two languages at a glance. For details, use the link to browse to the detailed topic.

> **Note** C++ and C# projects are derived from different project models. For information on the differences between C++ and C# projects, see Item Management in Projects and Using Solution Explorer.

Feature	Refer to the topic
Inheritance: A class can inherit implementation from one base class only. Also a class or an interface can implement multiple interfaces.	class interface
Arrays: The syntax of declaring C# arrays is different from that of C++ arrays. The tokens "[]" appear following the array type in C#.	Arrays
The **bool** type: There is no conversion between the **bool** type and other types (specifically **int**).	bool
The **long** type: In C#, the **long** data type is 64 bits, while in C++, it is 32 bits.	long
The **struct** type: In C#, classes and structs are semantically different. A **struct** is a value type, while a **class** is a reference type.	struct class
The **switch** statement: Unlike the C++ **switch** statement, C# does not support fall through from one case label to another.	switch
The **delegate** type: Delegates are roughly similar to function pointers in C++, but they are type-safe and secure.	delegate
Calling the overridden base class members from derived classes.	base See also the examples for override
Using the **new** modifier to explicitly hide an inherited member.	new
Declaring override methods requires the **override** keyword.	override
Preprocessor directives are used for conditional compilation. No header files are used in C#.	C# Preprocessor Directives
Exception handling: Using the **finally** statement.	try-finally try-catch-finally
C# operators: C# supports additional operators such as **is** and **typeof**. It also introduces different functionality of some logical operators.	& Operator | Operator ^ Operator is typeof
Use of the **extern** keyword.	extern
Use of the **static** keyword.	static
An alternative way to the C++ initialization list in constructing the base class.	See the examples for virtual
The general structure of the C# program: namespaces, classes, structs, delegates, and enumerations.	General Structure of a C# Program
The **Main** method is declared differently from the **main** function in C++. Also, compare the usage of the command-line arguments for each language.	Main
Method parameters: C# supports **ref** and **out** parameters, which are used instead of pointers in passing parameters by reference.	ref out
Pointers are allowed in C# but only in unsafe mode.	unsafe

Overloading operators is performed differently in C#.	C# Operators
Strings: C# strings are different from C++ strings.	string
The **foreach** keyword allows you to iterate through arrays and collections.	foreach, in
No global methods or variables in C#: Methods and variables must be contained within a type declaration (such as **class** or **struct**).	General Structure of a C# Program
No header files or #include directives in C#: The **using** directive is used to reference types in other namespaces without fully qualifying the type names.	using
Local variables in C# cannot be used before they are initialized.	5. Variables
Destructors: In C#, you don't have control over when a destructor is called because destructors are called automatically by the garbage collector.	Destructors
Constructors: Similar to C++, if you don't provide a class constructor in C#, a default constructor is automatically generated for you. The default constructor initializes all the fields to their default values.	Instance Constructors Default Values Table
C# does not support bit fields.	C++ Bit Fields
C# input/output services and formatting rely on the run-time library of the .NET Framework.	C# Language Tour Formatting Numeric Results Table
In C#, method parameters cannot have default values. Use method overloads if you want to achieve the same effect.	Compiler Error CS0241

For comparisons between C# and other programming languages, see the Language Equivalents documentation.

C# Compiler Options

The compiler produces executable (.exe) files, dynamic-link libraries (.dll), or code modules (.netmodule).

Every compiler option is available in two forms: **-***option* and **/***option*. The documentation only shows the **/***option* form.

In This Section

Building from the Command Line
Information about building a Visual C# application from the command line.
C# Compiler Options Listed by Category
A categorical listing of the compiler options.
C# Compiler Options Listed Alphabetically
An alphabetical listing of the compiler options.
Compiler Errors

Setting Visual C# Project Properties
Setting properties that govern how your project is compiled, built, and debugged. Includes information about custom build steps in Visual C# projects.
Default and Custom Builds
Information on build types and configurations.
Preparing and Managing Builds
Procedures for building within the Visual Studio development environment.

Building from the Command Line

The C# compiler can be invoked at the command line by typing the name of its executable file (csc.exe) on the command line. You may need to adjust your path if you want csc.exe to be invoked from any subdirectory on your computer.

This topic provides details on the following:

- Running VCVARS32.BAT
- Differences Between C# Compiler and C++ Compiler Output
- Rules for Command-Line Syntax
- Sample Command Lines

Running VCVARS32.BAT

vcvars32.bat sets the appropriate environment variables to enable command line builds.

To run VCVARS32.BAT

1. At the command prompt, change to the \bin subdirectory of your installation.
2. Run VCVARS32.bat by typing `VCVARS32`.

> **Caution** VCVARS32.bat can vary from machine to machine. Do not replace a missing or damaged VCVARS32.bat file with a VCVARS32.bat from another machine. Rerun setup to replace the missing file.

For more information about vcvars32.bat, see the following Knowledge Base article:

- Q248802 : Vcvars32.bat Generates Out of Environment Message

If the current version of Visual Studio is installed on a computer that also has a previous version of Visual Studio, you should not run vcvars32.bat from different versions in the same command window.

Differences Between C# Compiler and C++ Compiler Output

There are no object (.obj) files created as a result of invoking the C# compiler; output files are created directly. As a consequence of this, the C# compiler does not need a linker.

Rules for Command-Line Syntax

The C# compiler code uses the following rules when interpreting arguments given on the operating system command line:

- Arguments are delimited by white space, which is either a space or a tab.
- The caret character (^) is not recognized as an escape character or delimiter. The character is handled completely by the command-line parser in the operating system before being passed to the argv array in the program.
- A string surrounded by double quotation marks ("string") is interpreted as a single argument, regardless of white space contained within. A quoted string can be embedded in an argument.
- A double quotation mark preceded by a backslash (\") is interpreted as a literal double quotation mark character (").
- Backslashes are interpreted literally, unless they immediately precede a double quotation mark.
- If an even number of backslashes is followed by a double quotation mark, one backslash is placed in the argv array for every pair of backslashes, and the double quotation mark is interpreted as a string delimiter.
- If an odd number of backslashes is followed by a double quotation mark, one backslash is placed in the argv array for every pair of backslashes, and the double quotation mark is "escaped" by the remaining backslash, causing a literal double quotation mark (") to be placed in argv.

Sample Command Lines

- Compiles File.cs producing File.exe:

```
csc File.cs
```

- Compiles File.cs producing File.dll:

```
csc /target:library File.cs
```

- Compiles File.cs and creates My.exe:

```
csc /out:My.exe File.cs
```

- Compiles all of the C# files in the current directory, with optimizations on and defines the DEBUG symbol. The output is File2.exe:

```
csc /define:DEBUG /optimize /out:File2.exe *.cs
```

- Compiles all of the C# files in the current directory producing a debug version of File2.dll. No logo and no warnings are displayed:

```
csc /target:library /out:File2.dll /warn:0 /nologo /debug *.cs
```

- Compiles all of the C# files in the current directory to Something.xyz (a DLL):

```
csc /target:library /out:Something.xyz *.cs
```

C# Compiler Options | C# Compiler Options Listed Alphabetically | C# Compiler Options Listed by Category

C# Compiler Options Listed by Category

The following compiler options are sorted by category. For an alphabetical list, see C# Compiler Options Listed Alphabetically.

Optimization

Option	Purpose
/filealign	Specify the size of sections in the output file.
/optimize	Enable/disable optimizations.

Output Files

Option	Purpose
/doc	Process documentation comments to an XML file.
/out	Specify output file.
/target	Specify the format of the output file using one of four options: /target:exe /target:library /target:module /target:winexe

.NET Framework Assemblies

Option	Purpose
/addmodule	Specify one or more modules to be part of this assembly.
/lib	Specify the location of assemblies referenced by means of /reference.
/nostdlib	Do not import standard library (mscorlib.dll).
/reference	Import metadata from a file that contains an assembly.

Debugging/Error Checking

Option	Purpose
/bugreport	Create a file that contains information that makes it easy to report a bug.
/checked	Specify whether integer arithmetic that overflows the bounds of the data type will cause an exception at run time.
/debug	Emit debugging information.
/fullpaths	Specify the absolute path to the file in compiler output.
/nowarn	Suppress the compiler's ability to generate specified warnings.
/warn	Set warning level.
/warnaserror	Promote warnings to errors.

Preprocessor

Option	Purpose
/define	Define preprocessor symbols.

Resources

Option	Purpose
/linkresource	Create a link to a managed resource.
/resource	Embed a .NET Framework resource into the output file.
/win32icon	Insert an .ico file into the output file.
/win32res	Insert a Win32 resource into the output file.

Miscellaneous

Option	Purpose

@	Specify a response file.
/?	List compiler options to stdout.
/baseaddress	Specify the preferred base address at which to load a DLL.
/codepage	Specify the code page to use for all source code files in the compilation .
/help	List compiler options to stdout.
/incremental	Enable incremental compilation of source code files.
/main	Specify the location of the **Main** method.
/noconfig	Do not compile with csc.rsp.
/nologo	Suppress compiler banner information.
/recurse	Search subdirectories for source files to compile.
/unsafe	Compile code that uses the unsafe keyword.
/utf8output	Display compiler output using UTF-8 encoding.

C# Compiler Options | C# Compiler Options Listed by Category | Building from the Command Line

@ (Specify Response File)

```
@response_file
```

where:

response_file
A file that lists compiler options or source code files to compile.

Remarks

The @ option lets you specify a file that contains compiler options and source code files to compile. These compiler options and source code files will be processed by the compiler just as if they had been specified on the command line.

To specify more than one response file in a compilation, specify multiple response file options. For example:

```
@file1.rsp @file2.rsp
```

In a response file, multiple compiler options and source code files can appear on one line. A single compiler option specification must appear on one line (cannot span multiple lines). Response files can have comments that begin with the # symbol.

Specifying compiler options from within a response file is just like issuing those commands on the command line. See Building from the Command Line for more information.

The compiler processes the command options as they are encountered. Therefore, command line arguments can override previously listed options in response files. Conversely, options in a response file will override options listed previously on the command line or in other response files.

C# provides the csc.rsp file, which is located in the same directory as the csc.exe file. See /noconfig for more information on csc.rsp.

To set this compiler option in the Visual Studio development environment

This compiler option is unavailable in Visual Studio.

To set this compiler option programmatically

This compiler option cannot be changed programmatically.

Example

The following are a few lines from a sample response file:

```
# build the first output file
/target:exe /out:MyExe.exe source1.cs source2.cs
```

See Also

C# Compiler Options

/addmodule (Import Metadata)

```
/addmodule:file[;file2]
```

where:

file, *file2*
An output file that contains metadata. The file cannot contain an assembly manifest. To import more than one file, separate file names with either a comma or a semicolon.

Remarks

All modules added with **/addmodule** must be in the same directory as the output file at run time. That is, you can specify a module in any directory at compile time but the module must be in the application directory at run time. If the module is not in the application directory at run time, you will get a **System.TypeLoadException**.

file cannot contain an assembly. For example, if the output file was created with /target:module, its metadata can be imported with **/addmodule**.

If the output file was created with a **/target** option other than **/target:module**, its metadata cannot be imported with **/addmodule** but can be imported with /reference.

To set this compiler option in the Visual Studio development environment

This compiler option is unavailable in Visual Studio; a project cannot reference a module.

To set this compiler option programmatically

This compiler option cannot be changed programmatically.

Example

Compile source file `input.cs` and add metadata from `metad1.netmodule` and `metad2.netmodule` to produce `out.exe`:

```
csc /addmodule:metad1.netmodule;metad2.netmodule /out:out.exe input.cs
```

See Also

C# Compiler Options

/baseaddress (Specify Base Address of DLL)

```
/baseaddress:address
```

where:

address
The base address for the DLL. This address can be specified as a decimal, hexadecimal, or octal number.

Remarks

The **/baseaddress** option lets you specify the preferred base address at which to load a DLL. The default base address for a DLL is set by the .NET Framework common language runtime.

Be aware that the lower-order word in this address will be rounded. For example, if you specify 0x11110001, it will be rounded to 0x11110000.

To complete the signing process for a DLL, use –R of SN.EXE.

To set this compiler option in the Visual Studio development environment

1. Open the project's **Property Pages** dialog box. For details, see Setting Visual C# Project Properties.
2. Click the **Configuration Properties** folder.
3. Click the **Advanced** property page.
4. Modify the **Base Address** property.

To set this compiler option programmatically

See BaseAddress Property.

See Also

C# Compiler Options

/bugreport (Report a Problem)

```
/bugreport:file
```

where:

file
The name of the file that you want to contain your bug report.

Remarks

The **/bugreport** option will cause the following information to be placed in *file*:

- A copy of all source code files in the compilation.
- A listing of the compiler options used in the compilation.
- Version information about your compiler, runtime, and operating system.
- Referenced assemblies and modules (saved as hexadecimal digits), except assemblies that ship with the .NET Framework SDK.
- Compiler output, if any.
- A description of the problem, which you will be prompted for.
- A description of how you think the problem should be fixed, which you will be prompted for.

Because a copy of all source code files will be placed in *file*, you may want to reproduce the (suspected) code defect in the shortest possible program.

To set this compiler option in the Visual Studio development environment

This compiler option is unavailable in Visual Studio.

To set this compiler option programmatically

This compiler option cannot be changed programmatically.

Example

Compile `t2.cs` and put all bug reporting information in the file `problem.txt`:

```
csc /bugreport:problem.txt t2.cs
```

C# Compiler Options

/checked (Check Integer Arithmetic)

```
/checked[+ | -]
```

Remarks

The **/checked** option specifies whether an integer arithmetic statement that is not in the scope of the checked or unchecked keywords and that results in a value outside the range of the data type shall cause a run-time exception.

An integer arithmetic statement that is in the scope of the **checked** or **unchecked** keywords is not subject to the effect of the **/checked** option.

If an integer arithmetic statement that is not in the scope of the **checked** or **unchecked** keywords results in a value outside the range of the data type, and **/checked+** (**/checked**) is used in the compilation, then that statement will cause an exception at run time. If **/checked-** is used in the compilation, then that statement will not cause an exception at run time.

To set this compiler option in the Visual Studio development environment

1. Open the project's **Property Pages** dialog box. For details, see Setting Visual C# Project Properties.
2. Click the **Configuration Properties** folder.
3. Click the **Build** property page.
4. Modify the **Check for Arithmetic Overflow/Underflow** property.

To set this compiler option programmatically

See CheckForOverflowUnderflow Property.

Example

Compile `t2.cs` and specify that an integer arithmetic statement that is not in the scope of the **checked** or **unchecked** keywords and results in a value outside the range of the data type will cause an exception at run time.

```
csc t2.cs /checked
```

See Also

C# Compiler Options

/codepage (Specify Code Page for Source Code Files)

```
/codepage:id
```

where:

id
The id of the code page to use for all source code files in the compilation.

Remarks

If you compile one or more source code files that were not created to use the default code page on your computer, you can use the **/codepage** option to specify which code page should be used. **/codepage** applies to all source code files in your compilation.

If the source code files were created with the same codepage that is in effect on your computer or if the source code files were created with UNICODE or UTF-8, you need not use **/codepage**.

See GetCPInfo for information on how to find which code pages are supported on your system.

To set this compiler option in the Visual Studio development environment

This compiler option is unavailable in Visual Studio.

To set this compiler option programmatically

This compiler option cannot be changed programmatically.

See Also

C# Compiler Options

/debug (Emit Debugging Information)

```
/debug[+ | -]
/debug:{full | pdbonly}
```

where:

+ | -
Specifying +, or just **/debug**, causes the compiler to generate debugging information and place it in a program database (.pdb file). Specifying -, which is in effect if you do not specify **/debug**, causes no debug information to be created.

full | pdbonly
Specifies the type of debugging information generated by the compiler. The full argument, which is in effect if you do not specify **/debug:pdbonly**, enables attaching a debugger to the running program. Specifying pdbonly allows source code debugging when the program is started in the debugger but will only display assembler when the running program is attached to the debugger.

Remarks

The **/debug** option causes the compiler to generate debugging information and place it in the output file(s). Use this option to create debug builds. If **/debug**, **/debug+**, or **/debug:full** is not specified, you will not be able to debug the output file of your program.

For information on how to configure the debug performance of an application, see Making an Image Easier to Debug.

To set this compiler option in the Visual Studio development environment

1. Open the project's **Property Pages** dialog box. For details, see Setting Visual C# Project Properties.
2. Click the **Configuration Properties** folder.
3. Click the **Build** property page.
4. Modify the **Generate Debugging Information** property.

To set this compiler option programmatically

See DebugSymbols Property.

Example

Place debugging information in output file `app.exe`:

```
csc /debug /out:app.exe test.cs
```

See Also

C# Compiler Options

/define (Preprocessor Definition)

```
/define:name[;name2]
```

where:

name, *name2*
The name of one or more symbols that you want to define.

Remarks

The **/define** option defines *name* as a symbol in your program. It has the same effect as using a #define preprocessor directive in your source file. A symbol remains defined until an #undef directive in the source file removes the definition or the compiler reaches the end of the file.

You can use symbols created by this option with #if, #else, #elif, and #endif to compile source files conditionally.

/d is the short form of **/define**.

You can define multiple symbols with **/define** by using a semicolon or comma to separate symbol names. For example:

```
/define:DEBUG;TUESDAY
```

To set this compiler option in the Visual Studio development environment

1. Open the project's **Property Pages** dialog box. For details, see Setting Visual C# Project Properties.
2. Click the **Configuration Properties** folder.
3. Click the **Build** property page.
4. Modify the **Conditional Compilation Constants** property.

To set this compiler option programmatically

See DefineConstants Property.

Example

```
// preprocessor_define.cs
// compile with: /define:xx
// or uncomment the next line
// #define xx
using System;
public class Test
{
   public static void Main()
   {
      #if (xx)
         Console.WriteLine("xx exists");
      #else
         Console.WriteLine("xx does not exist");
      #endif
   }
}
```

See Also

C# Compiler Options

/doc (Process Documentation Comments)

```
/doc:file
```

where:

file
The output file for XML, which is populated with the comments in the source code files of the compilation.

Remarks

The **/doc** option allows you to place documentation comments in an XML file.

For Visual Studio .NET, only the C# compiler provides this documentation comments feature.

In source code files, documentation comments that precede the following can be processed and added to the XML file:

- Such user-defined types as a class, delegate, or interface
- Such members as a field, event, property, or method

The source code file that contains Main is output first into the XML.

To use the generated .xml file for use with the IntelliSense feature, let the file name of the .xml file be the same as the assembly you want to support and then make sure the .xml file is in the same directory as the assembly. Thus, when the assembly is referenced in the Visual Studio project, the .xml file is found as well.

/doc will be ignored in a compilation that uses /incremental; use /incremental- to ensure that *file* is up to date.

Unless you compile with /target:module, *file* will contain <assembly></assembly> tags specifying the name of the file containing the assembly manifest for the output file of the compilation.

See Recommended Tags for Documentation Comments for ways to generate documentation from comments in your code.

See the GotDotNet User Samples Search page (http://www.gotdotnet.com/userarea/keywordsrch.aspx?keyword=ansonh) for a sample of how to format an XML file.

See Commenting Code for information on how Visual Studio will display a report on the structure of your code, to include XML documentation comments.

To set this compiler option in the Visual Studio development environment

1. Open the project's **Property Pages** dialog box. For details, see Setting Visual C# Project Properties.
2. Click the **Configuration Properties** folder.
3. Click the **Build** property page.
4. Modify the **XML Documentation File** property.

To set this compiler option programmatically

See DocumentationFile Property.

Example

See XML Documentation Tutorial for a sample.

See Also

C# Compiler Options | XML Documentation Tutorial

/filealign (Specify Section Alignment)

```
/filealign:number
```

where:

number
A value that specifies the size of sections in the output file. Valid values are 512, 1024, 2048, 4096, and 8192. These values are in bytes.

Remarks

The **/filealign** option lets you specify the size of sections in your output file.

Each section will be aligned on a boundary that is a multiple of the **/filealign** value. There is no fixed default. If **/filealign** is not specified, the common language runtime picks a default at compile time.

By specifying the section size, you affect the size of the output file. Modifying section size may be useful for programs that will run on smaller devices.

Use DUMPBIN to see information about sections in your output file.

To set this compiler option in the Visual Studio development environment

1. Open the project's **Property Pages** dialog box. For details, see Setting Visual C# Project Properties.
2. Click the **Configuration Properties** folder.
3. Click the **Advanced** property page.
4. Modify the **File Alignment** property.

To set this compiler option programmatically

See FileAlignment Property.

See Also

C# Compiler Options

/fullpaths (Specify Absolute Path in Compiler Output)

```
/fullpaths
```

Remarks

By default, errors and warnings that result from compilation specify the name of the file in which an error was found. The **/fullpaths** option causes the compiler to specify the full path to the file.

To set this compiler option in the Visual Studio development environment

This compiler option is unavailable in Visual Studio.

To set this compiler option programmatically

This compiler option cannot be changed programmatically.

See Also

C# Compiler Options

/help, /? (Compiler Command-Line Help)

```
/help
/?
```

Remarks

This option sends a listing of compiler options, and a brief description of each option, to stdout. If this option is included in a compilation, no output file will be created and no compilation will take place.

To set this compiler option in the Visual Studio development environment

This compiler option is unavailable in Visual Studio.

To set this compiler option programmatically

This compiler option cannot be changed programmatically.

See Also

C# Compiler Options

/incremental (Enable Incremental Compilation)

```
/incremental[+ | -]
```

Remarks

The **/incremental** compiler option enables the incremental compiler, which compiles only those methods that have changed since the last compilation. Information about the state of the previous compilation is stored in the following files, which are created by the compiler:

output_file_name.dbg
When compiling with /debug, the status of debug information is stored in the program database (.pdb file).

output_file_name.extension.incr
Information about the status of the compilation, other than debug information, is stored in a .incr file.

The first time you use **/incremental**, the .incr and .pdb files are updated and all subsequent compilations will be incremental. Changing the compiler options from the previous **/incremental** compilation will cause a full rebuild of the .incr and .pdb files.

If the compiler detects many changes since the last incremental build, it may perform a full build, as a full build would be at least as efficient as an incremental build. If the compiler cannot find the project's .pdb or .incr files, a full rebuild will occur.

In an incremental build, /doc is ignored. To ensure that your documentation file is up to date, build with **/incremental-**.

By default, **/incremental-** is in effect. Specifying **/incremental** is the same as specifying **/incremental+**.

Output files created with the **/incremental** option may be larger than those created with incremental compilation disabled. Because the output files can be larger, you should use **/incremental-** in the final build of your output file.

/incremental will speed compilation on projects with many, smaller files, and will have little or no speed improvement on projects with fewer, large files.

To set this compiler option in the Visual Studio development environment

1. Open the project's **Property Pages** dialog box. For details, see Setting Visual C# Project Properties.
2. Click the **Configuration Properties** folder.
3. Click the **Advanced** property page.
4. Modify the **Incremental build** property.

To set this compiler option programmatically

See IncrementalBuild Property.

Example

Compile `in.cs` using the incremental compiler:

```
csc /incremental in.cs
```

See Also

C# Compiler Options

/lib (Specify Assembly Reference Locations)

```
/lib:dir1[, dir2]
```

where:

dir1
A directory for the compiler to look in if a referenced assembly is not found in the current working directory (the directory from which you are invoking the compiler) or in the common language runtime's system directory.

dir2
One or more additional directories to search in for assembly references. Separate additional directory names with a semicolon.

Remarks

The **/lib** option specifies the location of assemblies referenced by means of the /reference option.

The compiler searches for assembly references that are not fully qualified in the following order:

1. Current working directory. This is the directory from which the compiler is invoked.
2. The common language runtime system directory.
3. Directories specified by **/lib**.
4. Directories specified by the LIB environment variable.

Use /reference to specify an assembly reference.

/lib is additive; specifying it more than once appends to any prior values.

An alternative to using **/lib** is to copy into the working directory any required assemblies; this will allow you to simply pass the assembly name to **/reference**. You can then delete the assemblies from the working directory. Since the path to the dependent assembly is not specified in the assembly manifest, the application can be started on the target computer and will find and use the assembly in the global assembly cache.

Because the compiler can reference the assembly does not imply the common language runtime will be able to find and load the assembly at runtime. See How the Runtime Locates Assemblies for details on how the runtime searches for referenced assemblies.

To set this compiler option in the Visual Studio development environment

1. Open the project's **Property Pages** dialog box. For details, see Setting Visual C# Project Properties.
2. Click the **Common Properties** folder.
3. Click the **References Path** property page.
4. Modify the contents of the list box.

To set this compiler option programmatically

See ReferencePath Property.

Example

Compile t2.cs to create an .exe file. The compiler will look in the working directory and in the root directory of the C drive for assembly references.

```
csc /lib:c:\ /reference:t2.dll t2.cs
```

See Also

C# Compiler Options

/linkresource (Link to .NET Framework Resource)

```
/linkresource:filename[,identifier]
```

where:

filename
The .NET Framework resource file to which you want to link from the assembly.
identifier (optional)
The logical name for the resource; the name used to load the resource. The default is the name of the file name.

Remarks

The **/linkresource** option creates a link to a .NET Framework resource in the output file; the resource file is not placed in the output file. /resource embeds a resource file in the output file.

Linked resources are public in the assembly when created with the C# compiler.

/linkresource requires one of the /target options other than **/target:module**.

If *filename* is a .NET Framework resource file created, for example, by Resgen.exe or in the development environment, it can be accessed with members in the **System.Resources** namespace (see System.Resources.ResourceManager for more information). For all other resources, use the **GetManifestResource*** methods in the **System.Reflection.Assembly** class to access the resource at run time.

The file specified in *filename* can be any format. For example, you may want to make a native DLL part of the assembly, so it can be installed into the Global Assembly Cache and accessed from managed code in the assembly.

/linkres is the short form of **/linkresource**.

To set this compiler option in the Visual Studio development environment

This compiler option is unavailable in Visual Studio.

To set this compiler option programmatically

This compiler option cannot be changed programmatically.

Example

Compile `in.cs` and link to resource file `rf.resource`:

```
csc /linkresource:rf.resource in.cs
```

See Also

C# Compiler Options

/main (Specify Location of Main Method)

```
/main:class
```

where:

class
The type that contains the **Main** method.

Remarks

If your compilation includes more than one type with a Main method, you can specify which type contains the **Main** method that you want to use as the entry point into the program.

This option is for use when compiling an .exe file.

To set this compiler option in the Visual Studio development environment

1. Open the project's **Property Pages** dialog box. For details, see Setting Visual C# Project Properties.
2. Click the **Common Properties** folder.
3. Click the **General** property page.
4. Modify the **Startup Object** property.

To set this compiler option programmatically

See StartupObject Property.

Example

Compile `t2.cs` and `t3.cs`, specifying that the **Main** method will be found in `Test2`:

```
csc t2.cs t3.cs /main:Test2
```

See Also

C# Compiler Options

/noconfig (Ignore csc.rsp)

```
/noconfig
```

Remarks

The **/noconfig** option tells the compiler not to compile with the csc.rsp file, which is located and loaded from the same directory as the csc.exe file. The csc.rsp file references all the assemblies shipped with the .NET Framework. The actual references that the Visual Studio .NET development environment includes depend on the project type.

You can modify the csc.rsp file and specify additional compiler options that should be included in every compilation from the command line with csc.exe (except the **/noconfig** option).

The compiler processes the options passed to the **csc** command last. Therefore, any option on the command line overrides the setting of the same option in the csc.rsp file.

If you do not want the compiler to look for and use the settings in the csc.rsp file, specify **/noconfig**.

To set this compiler option in the Visual Studio development environment

This compiler option is unavailable in Visual Studio.

To set this compiler option programmatically

This compiler option cannot be changed programmatically.

See Also

C# Compiler Options

/nologo (Suppress Banner Information)

```
/nologo
```

Remarks

The **/nologo** option suppresses display of the sign-on banner when the compiler starts up and display of informational messages during compiling.

This option is not available from within the development environment; it is only available when compiling from the command line.

To set this compiler option in the Visual Studio development environment

This compiler option is unavailable in Visual Studio.

To set this compiler option programmatically

This compiler option cannot be changed programmatically.

See Also

C# Compiler Options

/nostdlib (Do Not Import Standard Library)

```
/nostdlib[+ | -]
```

Remarks

The **/nostdlib** option prevents the import of mscorlib.dll, which defines the entire System namespace. Use this option if you want to define or create your own System namespace and objects.

If you do not specify **/nostdlib**, mscorlib.dll will be imported into your program (same as specifying **/nostdlib-**). If you specify **/nostdlib**, it is the same as specifying **/nostdlib+**.

To set this compiler option in the Visual Studio development environment

1. Open the Property Pages dialog box for the project. For details, see Setting Visual C# Project Properties.
2. Click the **Configuration Properties** folder.
3. Click the **Advanced** property page.
4. Modify the **Do not use Mscorlib** property.

To set this compiler option programmatically

See NoStdLib.

See Also

C# Compiler Options

/nowarn (Suppress Specified Warnings)

```
/nowarn:number1[,number2[...]]
```

where:

number1, *number2*
A warning number that you want the compiler to suppress.

Remarks

The **/nowarn** option lets you suppress the compiler's ability to generate one or more warnings. Separate multiple warning numbers with a comma.

You only need to specify the numeric part of the warning identifier. For example, if you want to suppress CS0028, you could specify `/nowarn:28`.

The compiler will silently ignore warning numbers passed to **/nowarn** that were valid in previous releases, but that have been removed from the compiler. For example, CS0679 was valid in the compiler in Visual Studio .NET 2002 but was subsequently removed.

To set this compiler option in the Visual Studio development environment

1. Open the Property Pages dialog box for the project. For details, see Setting Visual C# Project Properties.
2. Click the **Configuration Properties** folder.
3. Click the **Build** property page.
4. Modify the **Suppress specific warnings** property.

To set this compiler option programmatically

See NoWarn.

See Also

C# Compiler Options

/optimize (Enable/Disable Optimizations)

```
/optimize[+ | -]
```

Remarks

The **/optimize** option enables or disables optimizations performed by the compiler to make your output file smaller, faster, and more efficient. **/optimize** also tells the common language runtime to optimize code at runtime.

By default, **/optimize-** is in effect. Specify **/optimize+** to enable optimizations.

When building a module to be used by an assembly, use the same **/optimize** settings as those of the assembly.

/o is the short form of **/optimize**.

It is possible to combine the **/optimize** and /debug options.

To set this compiler option in the Visual Studio development environment

1. Open the project's **Property Pages** dialog box. For details, see Setting Visual C# Project Properties.
2. Click the **Configuration Properties** folder.
3. Click the **Build** property page.
4. Modify the **Optimize code** property.

To set this compiler option programmatically

See Optimize Property.

Example

Compile `t2.cs` and enable compiler optimizations:

```
csc t2.cs /optimize
```

See Also

C# Compiler Options

/out (Set Output File Name)

```
/out:filename
```

where:

filename
The name of the output file created by the compiler.

Remarks

On the command line, it is possible to specify multiple output files for your compilation. The **/out** option specifies the name of the output file. The compiler expects to find one or more source code files following the **/out** option. Then, all source code files will be compiled into the output file specified by that **/out** option.

If you do not specify the name of the output file:

- An .exe will take its name from the source code file that contains the **Main** method.
- A .dll or .netmodule will take its name from the first source code file.

A source code file used to compile one output file cannot be used in the same compilation for the compilation of another output file.

When producing multiple output files in a command-line compilation, keep in mind that only one of the output files can be an assembly and that only the first output file specified (implicitly or explicitly with **/out**) can be the assembly.

Any modules produced as part of a compilation become files associated with any assembly also produced in the compilation. Use ildasm.exe to view the assembly manifest to see the associated files.

Specify the full name and extension of the file you want to create.

To set this compiler option in the Visual Studio development environment

1. Open the project's **Property Pages** dialog box. For details, see Setting Visual C# Project Properties.
2. Click the **Common Properties** folder.
3. Click the **General** property page.
4. Modify the **Assembly Name** property.

To set this compiler option programmatically

See OutputFileName Property.

Example

Compile `t.cs` and create output file `t.exe`, as well as build `t2.cs` and create module output file `mymodule.netmodule`:

```
csc t.cs /out:mymodule.netmodule /target:module t2.cs
```

See Also

C# Compiler Options

/recurse (Find Source Files in Subdirectories)

```
/recurse:[dir\]file
```

where:

dir (optional)
The directory in which you want the search to begin. If this is not specified, the search begins in the project directory.

file
The file(s) to search for. Wildcard characters are allowed.

Remarks

The **/recurse** option lets you compile source code files in all child directories of either the specified directory (*dir*) or of the project directory.

You can use wildcards in a file name to compile all matching files in the project directory without using **/recurse**.

To set this compiler option in the Visual Studio development environment

This compiler option is unavailable in Visual Studio.

To set this compiler option programmatically

This compiler option cannot be changed programmatically.

Example

Compiles all C# files in the current directory:

```
csc *.cs
```

Compiles all of the C# files in the dir1\dir2 directory and any directories below it and generates dir2.dll:

```
csc /target:library /out:dir2.dll /recurse: dir1\dir2\*.cs
```

See Also

C# Compiler Options

/reference (Import Metadata)

```
/reference:file[;file2]
```

where:

file, *file2*
One or more files that contain an assembly manifest. To import more than one file, separate file names with either a comma or a semicolon.

Remarks

The **/reference** option causes the compiler to make public type information in the specified files available to the project you are currently compiling.

The file(s) you import must contain a manifest; the output file must have been compiled with one of the /target options other than /target:module.

Use /addmodule to import metadata from an output file that does not contain an assembly manifest.

At run time, you should anticipate that only one .exe assembly can be loaded per process, even though, there may be times when more than one .exe might be loaded in the same process. Therefore, do not pass an assembly built with **/target:exe** or **/target:winexe** to **/reference**. This condition may be modified in future versions of the common language runtime.

If you reference an assembly (Assembly A), which itself references another assembly (Assembly B), you will need to reference Assembly B if:

- A type you use from Assembly A inherits from a type or implements an interface from Assembly B.
- If you invoke a field, property, event, or method that has a return type or parameter type from Assembly B.

Use /lib to specify the directory in which one or more of your assembly references is located. The **/lib** topic also discusses which directories the compiler searches for assemblies.

In order for the compiler to recognize a type in an assembly (not a module), it needs to be forced to resolve the type, which you can do, for example, by defining an instance of the type. There are other ways to resolve type names in an assembly for the compiler, for example, if you inherit from a type in an assembly, the type name will then become known to the compiler.

The csc.rsp response file, which references commonly-used .NET Framework assemblies, is used by default. Use /noconfig if you do not want the compiler to use csc.rsp.

/r is the short form of **/reference**.

To set this compiler option in the Visual Studio development environment

See Add Reference Dialog Box.

To set this compiler option programmatically

See Add Method (References Object).

Example

Compile source file `input.cs` and import metadata from `metad1.dll` and `metad2.dll` to produce `out.exe`:

```
csc /reference:metad1.dll;metad2.dll /out:out.exe input.cs
```

See Also

C# Compiler Options

/resource (Embed Resource File to Output)

```
/resource:filename[,identifier]
```

where:

filename
The .NET Framework resource file you want to embed in the output file.
identifier (optional)
The logical name for the resource; the name used to load the resource. The default is the name of the file name.

Remarks

Use /linkresource to link a resource to an assembly and not place the resource file in the output file.

Resources are public in the assembly when created with the C# compiler.

If *filename* is a .NET Framework resource file created, for example, by Resgen.exe or in the development environment, it can be accessed with members in the **System.Resources** namespace (see System.Resources.ResourceManager for more information). For all other resources, use the **GetManifestResource*** methods in the **System.Reflection.Assembly** class to access the resource at run time.

/res is the short form of **/resource**.

To set this compiler option in the Visual Studio development environment

1. Add a resource file to your project.
2. Select the file you want to embed in Solution Explorer.
3. Select **Build Action** for the file in the Properties window.
4. Set **Build Action** to **Embedded Resource**.

To set this compiler option programmatically

See BuildAction Property (Visual Basic and C# ProjectItem Object).

Example

Compile `in.cs` and attach resource file `rf.resource`:

```
csc /resource:rf.resource in.cs
```

See Also

C# Compiler Options

/target (Specify Output File Format)

The **/target** compiler option can be specified in one of four forms:

/target:exe
  Create an .exe file.
/target:library
  Create a code library.
/target:module
  Create a module.
/target:winexe
  Create a Windows program.

Unless you specify **/target:module**, **/target** causes a .NET Framework assembly manifest to be placed in an output file. See Global Attributes for information on how to specify assembly attributes.

The assembly manifest is placed in the first .exe output file in the compilation or in the first .dll, if there is no .exe output file. For example, in the following command line, the manifest will be placed in `1.exe`:

```
csc /out:1.exe t1.cs /out:2.netmodule t2.cs
```

The compiler creates only one assembly manifest per compilation. Information about all files in a compilation is placed in the assembly manifest. All output files except those created with **/target:module** can contain an assembly manifest. When producing multiple output files at the command line, only one assembly manifest can be created and it must go into the first output file specified on the command line. If the first output file is an exe (**/target:exe** or **/target:winexe**) or code library (**/target:library**), then any other output files produced in the same compilation must be modules (**/target:module**).

If you create an assembly, you can indicate that all or part of your code is CLS compliant with the CLSCompliant attribute.

```
// target_clscompliant.cs
[assembly:System.CLSCompliant(true)]   // specify assembly compliance

[System.CLSCompliant(false)]   // specify compliance for an element
class TestClass
{
   public static void Main()
   {
   }
}
```

To set this compiler option programmatically

See OutputType Property.

See Also

C# Compiler Options

/target:exe (Create a Console Application)

```
/target:exe
```

Remarks

The **/target:exe** option causes the compiler to create an executable (EXE), console application. The **/target:exe** option is in effect by default. The executable file will be created with the .exe extension.

Use /target:winexe to create a Windows program executable.

Unless otherwise specified with the /out option, the output file name takes the name of the input file that contains the Main method.

When specified at the command line, all files up to the next **/out**, **/target:winexe**, or /target:library option are used to create the .exe file. The **/target:exe** option is in effect for all files since the previous **/out** or **/target:library** option.

One and only one **Main** method is required in the source code files that are compiled into an .exe file. The /main compiler option lets you specify which class contains the **Main** method, in cases where your code has more than one class with a **Main** method.

To set this compiler option in the Visual Studio development environment

1. Open the project's **Property Pages** dialog box. For details, see Setting Visual C# Project Properties.
2. Click the **Common Properties** folder.
3. Click the **General** property page.
4. Modify the **Output Type** property.

To set this compiler option programmatically

See OutputType Property.

Example

Each of the following command lines will compile `in.cs`, creating `in.exe`:

```
csc /target:exe in.cs
csc in.cs
```

See Also

/target (Specify Output File Format) | C# Compiler Options

/target:library (Create a Code Library)

```
/target:library
```

Remarks

The **/target:library** option causes the compiler to create a dynamic-link library (DLL) rather than an executable file (EXE). The DLL will be created with the .dll extension.

Unless otherwise specified with the /out option, the output file name takes the name of the first input file.

When specified at the command line, all files up to the next **/out**, /target:winexe, or /target:exe option are used to create the .dll file.

When building a .dll file, a Main method is not required.

To set this compiler option in the Visual Studio development environment

1. Open the project's **Property Pages** dialog box. For details, see Setting Visual C# Project Properties.
2. Click the **Common Properties** folder.
3. Click the **General** property page.
4. Modify the **Output Type** property.

To set this compiler option programmatically

See OutputType Property.

Example

Compile `in.cs`, creating `in.dll`:

```
csc /target:library in.cs
```

See Also

/target (Specify Output File Format) | C# Compiler Options

/target:module (Create Module to Add to Assembly)

```
/target:module
```

Remarks

To not generate an assembly manifest, use the **/target:module** option. By default, the output file will have an extension of .netmodule.

A file that does not have an assembly manifest cannot be loaded by the .NET Framework common language runtime. However, such a file can be incorporated into the assembly manifest of an assembly by means of /addmodule.

If more than one module is created in a single compilation, internal types in one module will be available to other modules in the compilation. When code in one module references **internal** types in another module, then both modules must be incorporated into an assembly manifest, by means of **/addmodule**.

To set this compiler option in the Visual Studio development environment

Creating a module is not supported in the Visual Studio development environment.

To set this compiler option programmatically

See OutputType Property.

Example

Compile `in.cs`, creating `in.netmodule`:

```
csc /target:module in.cs
```

See Also

/target (Specify Output File Format) | C# Compiler Options

/target:winexe (Create a Windows Program)

```
/target:winexe
```

Remarks

The **/target:winexe** option causes the compiler to create an executable (EXE), Windows program. The executable file will be created with the .exe extension. A Windows program is one that provides a user interface from either the .NET Framework library or with the Win32 APIs.

Use /target:exe to create a console application.

Unless otherwise specified with the /out option, the output file name takes the name of the input file that contains the Main method.

When specified at the command line, all files until the next **/out** or /target option are used to create the Windows program.

One and only one **Main** method is required in the source code files that are compiled into an .exe file. The /main option lets you specify which class contains the **Main** method, in cases where your code has more than one class with a **Main** method.

To set this compiler option in the Visual Studio development environment

1. Open the project's **Property Pages** dialog box. For details, see Setting Visual C# Project Properties.
2. Click the **Common Properties** folder.
3. Click the **General** property page.
4. Modify the **Output Type** property.

To set this compiler option programmatically

See OutputType Property.

Example

Compile `in.cs` into a Windows program:

```
csc /target:winexe in.cs
```

See Also

/target (Specify Output File Format) | C# Compiler Options

/unsafe (Enable Unsafe Mode)

```
/unsafe
```

Remarks

The **/unsafe** option allows code that uses the unsafe keyword to compile.

To set this compiler option in the Visual Studio development environment

1. Open the project's **Property Pages** dialog box. For details, see Setting Visual C# Project Properties.
2. Click the **Configuration Properties** folder.
3. Click the **Build** property page.
4. Modify the **Allow unsafe code blocks** property.

To set this compiler option programmatically

See AllowUnsafeBlocks Property.

Example

Compile `in.cs` for unsafe mode:

```
csc /unsafe in.cs
```

See Also

C# Compiler Options

/utf8output (Display Compiler Messages with UTF-8)

```
/utf8output
```

Remarks

The **/utf8output** option displays compiler output using UTF-8 encoding.

In some international configurations, compiler output cannot correctly be displayed in the console. In these configurations, use **/utf8output** and redirect compiler output to a file.

To set this compiler option in the Visual Studio development environment

This compiler option is unavailable in Visual Studio.

To set this compiler option programmatically

This compiler option cannot be changed programmatically.

See Also

C# Compiler Options

/warn (Specify Warning Level)

```
/warn:option
```

where:

option
The minimum warning level you want displayed for the build. Valid values are 0-4:

Warning level	Meaning
0	Turns off emission of all warning messages.
1	Displays severe warning messages.
2	Displays level 1 warnings plus certain, less-severe warnings, such as warnings about hiding class members.
3	Displays level 2 warnings plus certain, less-severe warnings, such as warnings about expressions that always evaluate to **true** or **false**.
4	Displays all level 3 warnings plus informational warnings. This is the default warning level at the command line.

Remarks

The **/warn** option specifies the warning level for the compiler to display.

The Build Errors documentation describes the warnings, indicates each warning's level, and indicates potential problems (rather than actual coding errors) with statements that may not compile as you intend.

Use /warnaserror to treat all warnings as errors. Use /nowarn to disable certain warnings.

/w is the short form of **/warn**.

To set this compiler option in the Visual Studio development environment

1. Open the project's **Property Pages** dialog box. For details, see Setting Visual C# Project Properties.
2. Click the **Configuration Properties** folder.
3. Click the **Build** property page.
4. Modify the **Warning Level** property.

To set this compiler option programmatically

See WarningLevel Property.

Example

Compile `in.cs` and have the compiler only display level 1 warnings:

```
csc /warn:1 in.cs
```

See Also

C# Compiler Options

/warnaserror (Treat Warnings as Errors)

```
/warnaserror[+ | -]
```

Remarks

The **/warnaserror+** option treats all warnings as errors. Any messages that would ordinarily be reported as warnings are instead reported as errors, and the build process is halted (no output files are built).

By default, **/warnaserror-** is in effect, which causes warnings to not prevent the generation of an output file. **/warnaserror**, which is the same as **/warnaserror+**, causes warnings to be treated as errors.

Use /warn to specify the level of warnings that you want the compiler to display. Use /nowarn to disable certain warnings.

To set this compiler option in the Visual Studio development environment

1. Open the project's **Property Pages** dialog box. For details, see Setting Visual C# Project Properties.
2. Click the **Configuration Properties** folder.
3. Click the **Build** property page.
4. Modify the **Treat Warnings As Errors** property.

To set this compiler option programmatically

See TreatWarningsAsErrors Property.

Example

Compile `in.cs` and have the compiler display no warnings:

```
csc /warnaserror in.cs
```

See Also

C# Compiler Options

/win32icon (Import an .ico File)

```
/win32icon:filename
```

where:

filename
The .ico file that you want to add to your output file.

Remarks

The **/win32icon** option inserts an .ico file in the output file, which gives the output file the desired appearance in the Windows Explorer. An .ico file can be created with the Resource Compiler. The Resource Compiler is invoked when you compile a Visual C++ program; an .ico file is created from the .rc file.

See /linkresource (to reference) or /resource (to attach) a .NET Framework resource file. See /win32res to import a .res file.

To set this compiler option in the Visual Studio development environment

1. Open the project's **Property Pages** dialog box. For details, see Setting Visual C# Project Properties.
2. Click the **Common Properties** folder.
3. Click the **General** property page.
4. Modify the **Application Icon** property.

To set this compiler option programmatically

See ApplicationIcon Property.

Example

Compile `in.cs` and attach an .ico file `rf.ico` to produce `in.exe`:

```
csc /win32icon:rf.ico in.cs
```

See Also

C# Compiler Options

/win32res (Import a Win32 Resource File)

```
/win32res:filename
```

where:

filename
The resource file that you want to add to your output file.

Remarks

The **/win32res** option inserts a Win32 resource in the output file. A Win32 resource file can be created with the Resource Compiler. The Resource Compiler is invoked when you compile a Visual C++ program; a .res file is created from the .rc file.

A Win32 resource can contain version or bitmap (icon) information that would help identify your application in the Windows Explorer. If you do not specify **/win32res**, the compiler will generate version information based on the assembly version.

See /linkresource (to reference) or /resource (to attach) a .NET Framework resource file.

To set this compiler option in the Visual Studio development environment

This compiler option is unavailable in Visual Studio.

To set this compiler option programmatically

This compiler option cannot be changed programmatically.

Example

Compile `in.cs` and attach a Win32 resource file `rf.res` to produce `in.exe`:

```
csc /win32res:rf.res in.cs
```

Compiler Errors CS0001 Through CS9999

This section is a reference to the errors generated by the C# compiler. To get help on a particular error message, either click the mouse on an error number in the Output window and press F1, or type the error number in the **Look for** box in the Index.

See Also

C# Compiler Options

Compiler Error CS0001

Internal compiler error

Try to determine if the compiler is failing because of its inability to parse unexpected syntax. Then, contact Microsoft Product Support Services.

Compiler Error CS0003

Out of memory

The compiler was unable to allocate enough virtual memory to complete compilation. Close all unnecessary applications and compile again.

You may also want to increase the pagefile size and make sure you have free disk space.

This error may also appear as the result of having mismatched versions of the .NET Framework SDK and the C# compiler or one or more corrupt files that support the C# compiler; reinstall Visual Studio.

Compiler Error CS0004

Warning treated as error

You compiled with the /warnaserror compiler option, which causes the compiler to generate warnings as errors.

Compiler Error CS0005

Compiler option '*compiler_option*' must be followed by an argument

Some compiler options require parameters. If you do not pass the arguments required by the compiler option, CS0005 is generated.

For more information, see C# Compiler Options.

Compiler Error CS0006

Metadata file '*dll_name*' could not be found

The program was compiled and explicitly passed the name of a file that contained metadata; however, the .dll was not found.

Compiler Error CS0007

Unexpected common language runtime initialization error — '*description*'

The common language runtime installation may be corrupt.

Reinstall the common language runtime portion of your operating system.

Compiler Error CS0008

Unexpected error reading metadata from file '*file*' — '*description*'

A DLL was successfully opened for retrieving metadata but is corrupted, such that data could not be read from it.

Get an uncorrupted DLL to import.

Compiler Error CS0009

Metadata file '*file*' could not be opened — '*description*'

The file specified with the /reference compiler option does not contain valid metadata.

Compiler Error CS0010

Cannot declare a namespace and a type both named '*name*'

A user-defined namespace is conflicting with an imported type name.

For example, the following sample generates CS0010:

```
// CS0010.cs
namespace System.Byte   // CS0010, rename namespace
{
   class MyClass
   {
      public static int Main()
      {
         return(0);
      }
   }
}
```

Compiler Error CS0011

Referenced class '*class1*' has base class or interface '*base1*' defined in an assembly that is not referenced. You must add a reference to assembly '*assembly*'.

A class that was imported from a file with /reference, is derived from a class or implements an interface that is not found. This could occur if a required .DLL is not also included in the compilation with /reference.

See Add Reference Dialog Box for information on how to add a reference in the development environment.

The following sequence of compilations will result in CS0011:

```
// CS0011_1.cs
// compile with: /target:library
public class B1
{
}
```

Then:

```
// CS0011_2.cs
// compile with: /r:CS0011_1.dll /target:library
public class B2: B1
{
}
```

Then:

```
// CS0011_3.CS
// compile with: /r:CS0011_2.dll
// CS0011 expected
// to fix, compile with: /r:CS0011_1.dll;CS0011_2.dll
class D1
{
   public B2 b2 = null;
   public static void Main()
   {
   }
}
```

Compiler Error CS0012

The type '*type*' is defined in an assembly that is not referenced. You must add a reference to assembly '*assembly*'.

The definition for a referenced type was not found. This could occur if a required .DLL file is not included in the compilation.

The following sequence of compilations will result in a CS0012 error:

```
// cs0012a.cs
// compile with: /t:library
public class A
{
}
```

Then:

```
// cs0012b.cs
// compile with: /t:library /r:cs0012a.dll
public class B
{
   public static A f()
   {
      return new A();
   }
}
```

Then:

```
// cs0012c.cs
// compile with: /r:cs0012b.dll
class C
{
   public static void Main()
   {
      object o = B.f();   // CS0012
   }
}
```

You could resolve this CS0012 by compiling with `/r:b.dll;a.dll`.

Compiler Error CS0013

Unexpected error writing metadata to file '*file*' — '*description*'

The .NET Framework common language runtime failed to emit metadata. This could be a number of problems:

- Disk full.
- Corrupt Visual Studio installation; reinstall Visual Studio.
- Corrupt common language runtime; reinstall the common language runtime.

Compiler Error CS0014

Required file '*file*' could not be found

A file is needed by the compiler but is not on the system.

Compiler Error CS0015

The name of type '*type*' is too long

The fully qualified name of a user-defined type must be less than or equal to 2048 characters.

Compiler Error CS0016

Could not write to output file '*file*' — '*reason*'

The compiler could not write to an output file. The file may have read-only status.

Compiler Error CS0017

Program '*output file name*' has more than one entry point defined: *function*

A program can only have one Main method.

To resolve this error, you can either delete all Main methods in your code, except one, or you can use the /main compiler option to specify which Main method you want to use.

The following sample generates CS0017:

```
// CS0017.cs
public class clx
{
   static public void Main()
   {
   }
}

public class cly
{
   public static void Main()   // CS0017, delete one Main or use /main
   {
   }
}
```

Compiler Error CS0019

Operator '*operator*' cannot be applied to operands of type '*type*' and '*type*'

A binary operator is operating on data types for which it was not designed. For example, you cannot use the || operator on strings.

The following sample generates CS0019:

```
// CS0019.cs
public class MyClass
{
   [System.Diagnostics.ConditionalAttribute("DEBUG" || "TRACE")]   // CS0019
   // try the following line instead
   // [System.Diagnostics.ConditionalAttribute("DEBUG")]
   public void TestMethod()
   {
   }

   public static void Main()
   {
   }
}
```

In this example, conditional logic must be specified outside the **ConditionalAttribute**. You can only pass one predefined symbol to the **ConditionalAttribute**.

Compiler Error CS0020

Division by constant zero

An expression uses a literal (not variable) value of zero in the denominator of a division operation. Division by zero is not defined, and therefore invalid.

The following sample generates CS0020:

```
// CS0020.cs
namespace x
{
   public class b
   {
      public static void Main()
      {
         1 / 0;   // CS0020
      }
   }
}
```

Compiler Error CS0021

Cannot apply indexing with [] to an expression of type '*type*'

An attempt was made to access a value through an index operation on a data type that does not support array-like operations.

You may get CS0021 when trying to use an indexer in a C++ assembly. In this case, to decorate the C++ class with the DefaultMember attribute so the C# compiler knows which indexer is the default. For example,

```
[DefaultMember("Item")]
__gc public class StringBreaker: public IEnumerable {
   public:
   StringBreaker::StringBreaker(String* string);

   __property int get_Count();

      // indexer for the strings...
   __property String * get_Item(int index);
   __property void set_Item(int index, String* value);

   IEnumerator* GetEnumerator();

   private:
   ArrayList* entries;
};
```

The following sample generates CS0021. It consists of a .cpp file, which compiles to a .dll, and a .cs file that uses this .dll.

```
// CPP0021.cpp
// compile with: /clr /LD
#using <mscorlib.dll>
using namespace System;
using namespace System::Reflection;

// Adding this attribute solves the problem
//[DefaultMember("Item")]
//
__gc public class MyClassMC {
   public:
   // indexer Indexer for the strings...
   __property int get_Item(int index){  return index; }
   __property void set_Item(int index, int value) {};
};
```

The following is the C# file:

```
// CS0021b.cs
// compile with: /reference:CPP0021.dll
public class MyClass
{
   public static void Main()
   {
      MyClassMC i = new MyClassMC();
      i[2] = 10;   // CS0021
   }
}
```

Compiler Error CS0022

Wrong number of indices inside [], expected '*number*'

An array-access operation specified multiple indices where only one is allowed.

The following sample generates CS0022:

```
// CS0022.cs
public class MyClass
{
   public static void Main()
   {
      int[] a = new int[10];
      a[0] = 0;     // single-dimension array
      a[0,1] = 9;   // CS0022
   }
}
```

Compiler Error CS0023

Operator '*operator*' cannot be applied to operand of type '*type*'

An attempt was made to apply an operator to a variable whose type was not designed to work with the operator.

The following sample generates CS0023:

```
// CS0023.cs
namespace x
{
   public class a
   {
      public static void Main()
      {
         string s = "hello";
         s = -s;   // CS0023, minus operator not allowed on strings
      }
   }
}
```

Compiler Error CS0025

Standard library file '*file*' could not be found

A file that is needed by the compiler was not found. Check your path to ensure that the file is on the path. Also check that the file is on your computer.

You may need to reinstall Visual Studio to resolve this error.

Compiler Error CS0026

Keyword this is not valid in a static property, static method, or static field initializer

The this keyword is not allowed in static methods; you must have an instance before you can refer to an object with **this**.

The following sample generates CS0026:

```
// CS0026.cs
public class a
{
   public static int i = 0;

   public static void Main()
   {
      this.i = this.i + 1;   // CS0026
      // try the following line instead
      // i = i + 1;
   }
}
```

Compiler Error CS0027

Keyword this is not available in the current context

The this keyword was found outside of a property, method, or constructor.

The following sample generates CS0027:

```
// CS0027.cs
using System;
class CmyClass
{
   int err1 = this.fun() + 1;   // CS0027

   public int fun()
   {
      return 10;
   }

   public void x()
   {
      int err = this.fun() + 1;   // valid use of this
      Console.WriteLine(err);
   }

   public static void Main()
   {
      CMyClass c = new CMyClass();
      c.x();
   }
}
```

Compiler Warning (level 4) CS0028

'*function declaration*' has the wrong signature to be an entry point

The method declaration for Main was invalid.

The following sample generates CS0028:

```
// CS0028.cs
// compile with: /W:4 /warnaserror
public class a
{
   public static void Main(int i)   // CS0028
   // try the following line instead
   // public static void Main()
   {
   }
}
```

Compiler Error CS0029

Cannot implicitly convert type '*type*' to '*type*'

The compiler requires an explicit conversion. For example, you may need to cast an r-value to be the same type as an l-value. Or, you must provide conversion routines to support certain operator overloads.

Conversions must occur when assigning a variable of one type to a variable of a different type. When making an assignment between variables of different types, the compiler must convert the type on the right-hand side of the assignment operator to the type on the left-hand side of the assignment operator. Take the following the code:

```
int i = 50;
long lng = 100;
i = lng;
```

`i = lng;` makes an assignment, but the data types of the variables on the left and right-hand side of the assignment operator don't match. Before making the assignment the compiler is implicitly converting the variable `lng`, which is of type long, to an int. This is implicit because no code explicitly instructed the compiler to perform this conversion. The problem with this code is that this is considered a narrowing conversion, and the compiler does not allow implicit narrowing conversions because there could be a potential loss of data.

A narrowing conversion exists when converting to a data type that occupies less storage space in memory than the data type we are converting from. For example, converting a long to an int would be considered a narrowing conversion. A long occupies 8 bytes of memory while an int occupies 4 bytes. To see how data loss can occur, consider the following sample:

```
int i = 50;
long lng = 3147483647;
i = lng;
```

The variable `lng` now contains a value that cannot be stored in the variable `i` because it is too large. If we were to convert this value to an int type we would be losing some of our data and the converted value would not be the same as the value before the conversion.

A widening conversion would be the opposite of a narrowing conversion. With widening conversions, we are converting to a data type that occupies more storage space in memory than the data type we are converting from. Here is an example of a widening conversion:

```
int i = 50;
long lng = 100;
lng = i;
```

Notice the difference between this code sample and the first. This time the variable `lng` is on the left-hand side of the assignment operator, so it is the target of our assignment. Before the assignment can be made, the compiler must implicitly convert the variable `i`, which is of type int, to type long. This is a widening conversion since we are converting from a type that occupies 4 bytes of memory (an int) to a type that occupies 8 bytes of memory (a long). Implicit widening conversions are allowed because there is no potential loss of data. Any value that can be stored in an int can also be stored in a long.

We know that implicit narrowing conversions are not allowed, so to be able to compile this code we need to explicitly convert the data type. Explicit conversions are done using casting. Casting is the term used in C# to describe converting one data type to another. To get the code to compile we would need to use the following syntax:

```
int i = 50;
long lng = 100;
i = (int) lng;   // cast to int
```

The third line of code tells the compiler to explicitly convert the variable `lng`, which is of type long, to an int before making the assignment. Remember that with a narrowing conversion, there is a potential loss of data. Narrowing conversions should be used with caution and even though the code will compile you may get unexpected results at run-time.

This discussion has only been for value types. When working with value types you work directly with the data stored in the variable. However, the .NET Framework also has reference types. When working with reference types you are working with a reference to a variable, not the actual data. Examples of reference types would be classes, interfaces and arrays. You cannot

implicitly or explicitly convert one reference type to another unless the compiler allows the specific conversion or the appropriate conversion operators are implemented.

The following sample generates CS0029:

```
// CS0029.cs
public class MyInt
{
    private int x = 0;

    // Uncomment this conversion routine to resolve CS0029
    /*
    public static implicit operator int(MyInt i)
    {
       return i.x;
    }
    */

    public static void Main()
   {
      MyInt myInt = new MyInt();
      int i = myInt; // CS0029
   }
}
```

Compiler Error CS0030

Cannot convert type '*type*' to '*type*'

You must provide conversion routines to support certain operator overloads.

The following sample generates CS0030:

```
// CS0030.cs
namespace x
{
   public class iii
   {
      /*
      public static implicit operator iii(int aa)
      {
         return null;
      }

      public static implicit operator int(iii aa)
      {
         return 0;
      }
      */

      public static iii operator ++(iii aa)
      {
         return (iii)0;   // CS0030
         // uncomment the conversion routines to resolve CS0030
      }

      public static void Main()
      {
      }
   }
}
```

Compiler Error CS0031

Constant value '*value*' cannot be converted to a '*type*'

An attempt was made to assign a value to a variable whose type cannot store the value.

The following sample generates CS0031:

```
// CS0031.cs
namespace x
{
   public class a
   {
      public static void Main()
      {
         byte i = 512;   // CS0031, 512 cannot fit in byte
      }
   }
}
```

Compiler Error CS0032

Could not open incremental build file '*file*' for writing

During an incremental build (/incremental), the compiler could not open the output file. The output file may have read-only status, which you should change to read/write status.

Compiler Error CS0033

Out of disk space or I/O error writing incremental build file '*file*'

During an incremental build (/incremental), the compiler writes to a file containing dependency information used to make rebuild information faster. This write could fail. Perhaps the file had read-only status, which you should change to read/write status.

Compiler Error CS0034

Operator '*operator*' is ambiguous on operands of type '*type1*' and '*type2*'

An operator was used on two objects and the compiler found more than one conversion. Conversions need to be unique, so you either need to make a cast or to make one of the conversions explicit.

The following sample generates CS0034:

```
// CS0034.cs
public class A
{
   // allows for the conversion of A object to int
   public static implicit operator int (A s)
   {
      return 0;
   }

   public static implicit operator string (A i)
   {
      return null;
   }
}

public class B
{
   public static implicit operator int (B s)
   // one way to resolve this CS0034 is to make one conversion explicit
   // public static explicit operator int (B s)
   {
      return 0;
   }

   public static implicit operator string (B i)
   {
      return null;
   }

   public static implicit operator B (string i)
   {
      return null;
   }

   public static implicit operator B (int i)
   {
      return null;
   }
}

public class C
{
   public static void Main ()
   {
      A a = new A();
      B b = new B();
      b = b + a;   // CS0034
      // another way to resolve this CS0034 is to make a cast
      // b = b + (int)a;
   }
}
```

Compiler Error CS0035

Operator '*operator*' is ambiguous on an operand of type '*type*'

The compiler has more than one available conversion and does not know which to choose before applying the operator.

The following sample generates CS0035:

```
// CS0035.cs
class MyClass
{
   private int i;

   public MyClass(int i)
   {
      this.i = i;
   }

   public static implicit operator double(MyClass x)
   {
      return (double) x.i;
   }

   public static implicit operator decimal(MyClass x)
   {
      return (decimal) x.i;
   }
}

class MyClass2
{
   static void Main()
   {
      MyClass x = new MyClass(7);
      object o = - x;   // CS0035
      // try a cast:
      // object o = - (double)x;
   }
}
```

Compiler Error CS0036

An out parameter cannot have the '[In]' attribute

Currently, the **In** attribute is not permitted on an out parameter.

The following sample generates CS0036:

```
// CS0036.cs

using System;
using System.Runtime.InteropServices;

public class MyClass
{
   public static void TestOut([In] out char TestChar)   // CS0036
   // try the following line instead
   // public static void TestOut(out char TestChar)
   {
      TestChar = 'b';
      Console.WriteLine(TestChar);
   }

   public static void Main()
   {
      char i;           // variable need not be initialized
      TestOut(out i);   // the arg must be passed as out
      Console.WriteLine(i);
   }
}
```

Compiler Error CS0037

Cannot convert null to '*type*' because it is a value type

The compiler cannot assign null to a value type; null can only be assigned to a reference type. struct is a value type.

The following sample generates CS0037:

```
// CS0037.cs
public struct s
{
}

class a
{
   public static void Main()
   {
      int i = null;   // CS0037
      s ss = null;    // CS0037
   }
}
```

Compiler Error CS0038

Cannot access a nonstatic member of outer type '*type1*' via nested type '*type2*'

A field in a class is not automatically available to a nested class. To be available to a nested class, the field must be static. Otherwise, you must create an instance of the outer class.

The following sample generates CS0038:

```
// CS0038.cs
class OuterClass
{
   public int count;
   // try the following line instead
   // public static int count;

   class InnerClass
   {
      void func()
      {
         // or, create an instance
         // OuterClass class_inst = new OuterClass();
         // int count2 = class_inst.count;
         int count2 = count;   // CS0038
      }
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0039

Cannot convert type '*type1*' to '*type2*'

A conversion with the as operator is only allowed by inheritance.

The following sample generates CS0039:

```
// CS0039.cs
using System;

class A
{
}

class B: A
{
}

class C: A
{
}

class M
{
   static void Main()
   {
      A a = new C();
      B b = new B();
      C c;

      c = a as C;  // valid, there is a built-in reference
                   // conversion from A to C.

      c = b as C;  // CS0039, there is no built-in reference
                   // conversion from B to C.
   }
}
```

Compiler Error CS0040

Unexpected debug information initialization error — '*reason*'

This error can occur when using the /debug compiler option and indicates that the compiler was unable to write to the .pdb file. Possible resolutions to this error include reinstalling Visual Studio, ensuring that the compiler has write access to a file or directory, or not compiling with /debug.

Compiler Error CS0041

Unexpected error writing debug information to file '*file*' — '*reason*'

This error can occur when using the /debug compiler option. If you are unable to resolve the error based on the information in *reason*, do not compile with /debug.

Compiler Error CS0042

Unexpected error creating debug information file '*file*' — '*reason*'

The compiler could not create the debug information; *reason* contains additional information on the error condition.

Compiler Error CS0043

PDB file '*file*' has an incorrect or out-of-date format. Delete it and rebuild.

Delete the .pdb file for this compilation and recompile.

Compiler Error CS0050

Inconsistent accessibility: return type '*type*' is less accessible than method '*method*'

The return type and each of the types referenced in the formal parameter list of a method must be at least as accessible as the method itself (see 3.5.4 Accessibility constraints).

The following sample generates CS0050:

```
// CS0050.cs
class MyClass
// try the following line instead
// public class MyClass
{
}

public class MyClass2
{
   public static MyClass MyMethod() // CS0050
   {
      return new MyClass();
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0051

Inconsistent accessibility: parameter type '*type*' is less accessible than method '*method*'

The return type and each of the types referenced in the formal parameter list of a method must be at least as accessible as the method itself (see 3.5.4 Accessibility constraints).

The following sample generates CS0051:

```
// CS0051.cs
class A
// try the following line instead
// public class A
{
   public static implicit operator A(int i)
   {
      return null;
   }
}

class B
// try the following line instead
// public class B
{
   public static implicit operator B(int i)
   {
      return null;
   }
}

public class C
{
   public void f (A a)
   {
   }

   public void f (B b)
   {
   }

   public static void Main ()
   {
      C c = new C();
      c.f((A)5);     // CS0051, could convert either to A or B
   }
}
```

Compiler Error CS0052

Inconsistent accessibility: field type '*type*' is less accessible than field '*field*'

A public construct must return a publicly accessible object.

The following sample generates CS0052:

```
// CS0052.cs
class MyClass
// try the following line instead
// public class MyClass
{
}

public class MyClass2
{
   public MyClass mf;   // CS0052
}

public class MyClass3
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0053

Inconsistent accessibility: property type '*type*' is less accessible than property '*property*'

A public construct must return a publicly accessible object.

The following sample generates CS0053:

```
// CS0053.cs
class MyClass
// try the following line instead
// public class MyClass
{
}

public class MyClass2
{
   public MyClass MyProperty   // CS0053
   {
      get
      {
         return new MyClass();
      }
      set
      {
      }
   }
}

public class MyClass3
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0054

Inconsistent accessibility: indexer return type '*type*' is less accessible than indexer '*indexer*'

A public construct must return a publicly accessible object.

The following sample generates CS0054:

```
// CS0054.cs
class MyClass
// try the following line instead
// public class MyClass
{
}

public class MyClass3
{
   public MyClass this[int i]   // CS0054
   {
      get
      {
         return new MyClass();
      }
   }
}

public class MyClass2
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0055

Inconsistent accessibility: parameter type '*type*' is less accessible than indexer '*indexer*'

A public construct must return a publicly accessible object.

The following sample generates CS0055:

```
// CS0055.cs
class MyClass
// try the following line instead
// public class MyClass
{
}

public class MyClass2
{
   public int this[MyClass i]   // CS0055
   {
      get
      {
         return 0;
      }
   }
}

public class MyClass3
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0056

Inconsistent accessibility: return type '*type*' is less accessible than operator '*operator*'

A public construct must return a publicly accessible object.

The following sample generates CS0056:

```
// CS0056.cs
class ii
// try the following line instead
// public class ii
{
}

public class a
{
   public static implicit operator ii(a aa)   // CS0056
   {
      return new ii();
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0057

Inconsistent accessibility: parameter type '*type*' is less accessible than operator '*operator*'

A public construct must return a publicly accessible object.

The following sample generates CS0057:

```
// CS0057.cs
class MyClass
// try the following line instead
// public class MyClass
{
}

public class MyClass2
{
   public static implicit operator MyClass2(MyClass iii)   // CS0057
   {
      return new MyClass2();
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0058

Inconsistent accessibility: parameter type '*type*' is less accessible than delegate '*delegate*'

A public construct must return a publicly accessible object.

The following sample generates CS0058:

```
// CS0058.cs
class MyClass
// try the following line instead
// public class MyClass
{
}

public delegate MyClass MyClassDel();   // CS0058

public class a
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0059

Inconsistent accessibility: parameter type '*type*' is less accessible than delegate '*delegate*'

The return type and each of the types referenced in the formal parameter list of a method must be at least as accessible as the method itself (see 3.5.4 Accessibility constraints).

The following sample generates CS0059:

```
// CS0059.cs
class MyClass
// try the following line instead
// public class MyClass
{
}

public delegate void MyClassDel( MyClass iii);   // CS0059

public class a
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0060

Inconsistent accessibility: base class '*class1*' is less accessible than class '*class2*'

Class accessibility should be consistent between the base class and inherited class.

The following sample generates CS0060:

```
// CS0060.cs
class MyClass
// try the following line instead
// public class MyClass
{
}

public class MyClass2 : MyClass   // CS0060
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0061

Inconsistent accessibility: base interface '*interface 1*' is less accessible than interface '*interface 2*'

A public construct must return a publicly accessible object.

Interface accessibility cannot be narrowed in a derived interface.

The following sample generates CS0061:

```
// CS0061.cs
// resolve this CS0061 by either making a public and b internal
// or by making both interfaces internal
internal interface a
{
   void mf();
}

public interface b : a   // CS0061
{
   new void mf();
}

class x
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0065

'*event*' : event property must have both add and remove accessors

An event that is not a field must have both access methods.

The following sample generates CS0065:

```
// CS0065.cs
using System;
public delegate void Eventhandler(object sender, int e);
public class MyClass
{
   public event EventHandler Click   // CS0065,
   {
      // uncomment the add and remove definitions
      /*
      add
      {
         Click += value;
      }
      remove
      {
         Click -= value;
      }
      */
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0066

'*event*': event must be of a delegate type

This declaration must be a delegate type.

The following sample generates CS0066:

```
// CS0066.cs
using System;

public class EventHandler
{
}

// try the following declaration for EventHandler (deleting the EventHandler class)
// public delegate void EventHandler();

public class a
{
   public event EventHandler Click;   // CS0066

   private void TestMethod()
   {
      if (Click != null)
         Click();
   }

   public static void Main()
   {
   }
}
```

Compiler Warning (level 3) CS0067

The event '*event*' is never used

An event was declared but never used in the class in which it was declared.

The following sample generates CS0067:

```
// CS0067.cs
// compile with: /W:3
using System;
delegate void MyDelegate();

class MyClass
{
   public event MyDelegate evt;   // CS0067
   // uncomment TestMethod to resolve this CS0067
/*
   private void TestMethod()
   {
      if (evt != null)
         evt();
   }
*/
   public static void Main()
   {
   }
}
```

Compiler Error CS0068

'*event*': event in interface cannot have initializer

An event in an interface cannot have an initializer.

The following sample generates CS0068:

```
// CS0068.cs

delegate void MyDelegate();

interface I
{
   event MyDelegate d = new MyDelegate(M.f);   // CS0068
   // try the following line instead
   // event MyDelegate d2;
}

class M
{
   event MyDelegate d = new MyDelegate(M.f);

   public static void f()
   {
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0069

'*event*': event in interface cannot have add or remove accessors

You cannot define an event's accessor functions in an interface.

The following sample generates CS0069:

```
// CS0069.cs
using System;
public delegate void EventHandler();

public interface a
{
   event EventHandler Click   // CS0069
   {
      add
      {
      }
      remove
      {
      }
   }
   // remove the preceding EventHandler block
   // try the following line instead
   // event EventHandler Click;
}

public class Class1
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0070

The event '*event*' can only appear on the left hand side of += or -= (except when used from within the type '*type*')

Outside of the class it is defined in, an event can only add or subtract references.

The following sample generates CS0070:

```
// CS0070.cs
using System;
public delegate void EventHandler();

public class A
{
   public event EventHandler Click;

   public static void OnClick()
   {
      EventHandler eh;
      A a = new A();
      eh = a.Click;
   }

   public static void Main()
   {
   }
}

public class B
{
   public int mf ()
   {
      EventHandler eh = new EventHandler(A.OnClick);
      A a = new A();
      eh = a.Click;   // CS0070
      // try the following line instead
      // a.Click += eh;
      return 1;
   }
}
```

Compiler Error CS0071

An explicit interface implementation of an event must use property syntax

When implementing an event that was declared in an interface, you must use property syntax.

The following sample generates CS0071:

```
// CS0071.cs
public delegate void MyEvent(object sender);

interface Itest
{
   event MyEvent Clicked;
}

class Test : Itest
{
   event MyEvent ITest.Clicked()   // CS0071
   {
   }

   // try the following code instead
   /*
   event MyEvent ITest.Clicked
   {
      get
      {
         return null;
      }
      set
      {
      }
   }
   */

   public static void Main()
   {
   }
}
```

Compiler Error CS0072

'*event*' : cannot override; '*method*' is not an event

An event can only override another event.

The following sample generates CS0072:

```
// CS0072.cs
delegate void del();

class Test1
{
   public virtual event del MyEvent;
   public virtual void VMeth()
   {
   }

   public void FireAway()
   {
      if (MyEvent != null)
         MyEvent();
   }
}

class Test2 : Test1
{
   public override event del VMeth   // CS0072
   // uncomment the following lines to resolve
   // public override event del MyEvent
   {
      add
      {
         VMeth += value;
         // MyEvent += value;
      }
      remove
      {
         VMeth -= value;
         // MyEvent -= value;
      }
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0073

An add or remove accessor must have a body

An **add** or **remove** keyword in an event definition must have a body.

The following sample generates CS0073:

```
// CS0073.cs
delegate void del();

class Test
{
   public event del MyEvent
   {
      add;   // CS0073
      // try the following lines instead
      // add
      // {
      //    MyEvent += value;
      // }
      remove
      {
         MyEvent -= value;
      }

   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0074

'*event*': abstract event cannot have initializer

If an event is marked as **abstract**, it cannot be initialized.

The following sample generates CS0074:

```
// CS0074.cs
delegate void D();

abstract class Test
{
   public abstract event D e = null;   // CS0074
   // try the following line instead
   // public abstract event D e;

   public static void Main()
   {
   }
}
```

Compiler Error CS0075

To cast a negative value, you must enclose the value in parentheses

Values that you want to cast must be in parentheses.

The following sample generates CS0075:

```
// CS0075.cs
using System;

enum Myint : long
{
   three = 3L,
}

class test
{
   public static void Main(String [] args )
   {
      Myint i = (Myint) -1 ;   // CS0075
      // try the following line instead
      // Myint i = (Myint) (-1) ;
      i++;
   }
}
```

Compiler Error CS0076

The enumerator name 'value__' is reserved and cannot be used

An item in an enumeration cannot have an identifier called **value__**.

The following sample generates CS0076:

```
// CS0076.cs
using System;

enum Myint : long
{
   value__ = 3L   // CS0076, cannot use the name value__
}

class MyClass
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0077

The as operator must be used with a reference type ('*type*' is a value type)

The as operator was passed a value type. Because **as** can return null, it can only be passed reference types.

The following sample generates CS0077:

```
// CS0077.cs
using System;

class C
{
}

struct S
{
}

class M
{
   public static void Main()
   {
      object o1, o2;
      C c;
      S s;

      o1 = new C();
      o2 = new S();

      s = o2 as S;  // CS0077, S is not a reference type.
      // try the following line instead
      // c = o1 as C;
   }
}
```

Compiler Warning (level 4) CS0078

The 'l' suffix is easily confused with the digit '1' -- use 'L' for clarity

The compiler warns when it detects a cast to long using a lowercase l instead of an uppercase L.

The following sample generates CS0078:

```
// CS0078.cs
// compile with: /W:4
class test {
   public static void TestL(long i)
   {
   }

   public static void TestL(int i)
   {
   }

   public static void Main()
   {
      TestL(25l);   // CS0078
      // try the following line instead
      // TestL(25L);
   }
}
```

Compiler Error CS0079

The event '*event*' can only appear on the left hand side of += or -=

An event was called incorrectly.

The following sample generates CS0079:

```
// CS0079.cs
using System;

public delegate void MyEventHandler();

public class Class1
{
   private MyEventHandler _e;

   public event MyEventHandler Pow
   {
      add
      {
         _e += value;
         Console.WriteLine("in add accessor");
      }
      remove
      {
         _e -= value;
         Console.WriteLine("in remove accessor");
      }
   }

   public void Handler()
   {
   }

   public void Fire()
   {
      if (_e != null)
      {
         Pow();   // CS0079
         // try the following line instead
         // _e();
      }
   }

   public static void Main()
   {
      Class1 p = new Class1();
      p.Pow += new MyEventHandler(p.Handler);
      p._e();
      p.Pow += new MyEventHandler(p.Handler);
      p._e();
      p._e -= new MyEventHandler(p.Handler);
      if (p._e != null)
      {
         p._e();
      }
      p.Pow -= new MyEventHandler(p.Handler);
      if (p._e != null)
      {
         p._e();
      }
   }
}
```

Compiler Error CS0100

The parameter name '*parameter name*' is a duplicate

A method declaration used the same parameter name more than once. Parameter names must be unique in a method declaration.

The following sample generates CS0100:

```
// CS0100.cs
namespace x
{
   public class a
   {
      public static void f(int i, char i)   // CS0100
      // try the following line instead
      // public static void f(int i, char j)
      {
      }

      public static void Main()
      {
      }
   }
}
```

Compiler Error CS0101

The namespace '*namespace*' already contains a definition for '*type*'

A namespace has duplicate identifiers. Rename or delete one of the duplicate identifiers.

The following sample generates CS0101:

```
// CS0101.cs
namespace x
{
   public class clx
   {
      static public void Main()
      {
      }
   }

   public class clx   // CS0101
   {
   }
}
```

Compiler Error CS0102

The class '*class*' already contains a definition for '*identifier*'

A class contains multiple declarations for identifiers with the same name; delete or rename one of the duplicate identifiers.

The following sample generates CS0102:

```
// CS0102.cs
namespace x
{
   abstract public class clx
   {
      int i;

      enum splitch : int
      {
         x, x   // CS0102
      };

      public static int Main()
      {
         return 0;
      }
   }
}
```

Compiler Error CS0103

The name '*name*' does not exist in the class or namespace '*namespace*'

An attempt was made to use a name that does not exist in the class or the namespace.

The following sample generates CS0103:

```
// CS0103.cs
using System;

class MyClass
{
   public static void Main()
   {
      // MyClass test = null;
      try
      {
         MyClass conn = new MyClass();   // delete this line
         // and uncomment the following line and the line above the try
         // conn = new MyClass();
      }
      catch(Exception e)
      {
         if (conn != null)   // CS0103
            Console.WriteLine("{0}", e);
      }
   }
}
```

Compiler Error CS0104

'*reference*' is an ambiguous reference

Your program contains using directives for two namespaces and your code references a name that appears in both namespaces.

The following sample generates CS0104:

```
// CS0104.cs
using x;
using y;

namespace x
{
   public class Test
   {
   }
}

namespace y
{
   public class Test
   {
   }
}

public class a
{
   public static void Main()
   {
      Test test = new Test();   // CS0104, is Test in x or y namespace?
      // try the following line instead
      // y.Test test = new y.Test();
   }
}
```

Compiler Warning (level 3) CS0105

The using directive for '*namespace*' appeared previously in this namespace

A namespace, which should only be declared once, was declared more than once; remove all duplicate namespace declarations.

The following sample generates CS0105:

```
// CS0105.cs
// compile with: /W:3
using System;
using System;   // CS0105

public class a
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0106

The modifier '*modifier*' is not valid for this item

A class or interface member was marked with an invalid access modifier. For example:

- The static and public modifiers are not permitted on interface methods.
- The **static** modifier is not permitted on a class.
- The **public** keyword is not allowed on an explicit interface declaration. In this case, remove the **public** keyword from the explicit interface declaration.
- The abstract keyword is not allowed on an explicit interface declaration because an explicit interface implementation could never be overridden.

The following sample generates CS0106:

```
// CS0106.cs
namespace MyNamespace
{
   interface I
   {
      void m();
      static public void f();   // CS0106
   }

   public class MyClass
   {
      public void I.m()   // CS0106
      {
      }

      public static void Main()
      {
      }
   }
}
```

Compiler Error CS0107

More than one protection modifier

Only one access modifier (public, private, protected, or internal) is allowed on a class member, with the exception of except **internal protected**.

The following sample generates CS0107:

```
// CS0107.cs
public class C
{
   private internal void f()   // CS0107, delete private or internal
   {
   }

   public static int Main()
   {
      return 1;
   }
}
```

Compiler Warning (level 2) CS0108

The keyword new is required on '*member1*' because it hides inherited member '*member2*'

A variable was declared with the same name as a variable in a base class. However, the new keyword was not used. This warning informs you that you should use **new**; the variable is declared as if **new** had been used in the declaration.

The following sample generates CS0108:

```
// CS0108.cs
// compile with: /W:2
using System;

namespace x
{
   public class clx
   {
      public int i = 1;
   }

   public class cly : clx
   {
      public static int i = 2;   // CS0108, use the new keyword
      // the compiler parses the previous line as if you had specified:
      // public static new int i = 2;

      public static void Main()
      {
         Console.WriteLine(i);
      }
   }
}
```

Compiler Warning (level 4) CS0109

The member '*member*' does not hide an inherited member. The new keyword is not required

A class declaration included the new keyword even though the declaration does not override an existing declaration in a base class. You can delete the **new** keyword.

The following sample generates CS0109:

```
// CS0109.cs
// compile with: /W:4
namespace x
{
   public class a
   {
      public int i;
   }

   public class b : a
   {
      public new int i;
      public new int j;   // CS0109
      public static void Main()
      {
      }
   }
}
```

Compiler Error CS0110

The evaluation of the constant value for '*const declaration*' involves a circular definition

The declaration of a const variable (`a`) cannot reference another const variable (`b`) that also references (`a`).

The following sample generates CS0110:

```
// CS0110.cs
namespace x
{
   public class a
   {
      public static void Main()
      {
      }
   }

   public class b : a
   {
      public const int i = c + 1;   // CS0110, c already references i
      public const int c = i + 1;
      // the following line would be OK
      // public const int c = 10;
   }
}
```

Compiler Error CS0111

Class '*class*' already defines a member called '*member*' with the same parameter types

A class contains two identical member declarations.

The following sample generates CS0111:

```
// CS0111.cs
namespace x
{
   abstract public class clx
   {
      public abstract void f();
   }

   public class cly : clx
   {
      public void f()
      {
      }
      override public void f() // CS0111, duplicate declaration
      {
      }
      public static int Main()
      {
         return 0;
      }
   }
}
```

Compiler Error CS0112

A static member '*function*' cannot be marked as override, virtual or abstract

Any method declaration that uses the **override**, **virtual**, or **abstract** keyword cannot also use the **static** keyword.

For more information, see Modifiers.

The following sample generates CS0112:

```
// CS0112.cs
namespace x
{
   abstract public class clx
   {
      public abstract void f();
   }

   public class cly : clx
   {
      override public static void f()   // CS0112, remove static keyword
      {
      }

      public static int Main()
      {
         return 0;
      }
   }
}
```

Compiler Error CS0113

A member '*function*' marked as override cannot be marked as new or virtual

It is mutually exclusive to mark a method with the new and override keywords.

The following sample generates CS0113:

```
// CS0113.cs
namespace x
{
   abstract public class clx
   {
      public abstract void f();
   }

   public class cly : clx
   {
      override new public void f()   // CS0113, remove new keyword
      {
      }

      public static int Main()
      {
         return 0;
      }
   }
}
```

Compiler Warning (level 2) CS0114

'*function1*' hides inherited member '*function2*'. To make the current method override that implementation, add the override keyword. Otherwise add the new keyword.

A declaration in a class conflicts with a declaration in a base class such that the base class member will be hidden.

For more information, see base.

The following sample generates CS0114:

```
// CS0114.cs
// compile with: /W:2 /warnaserror
abstract public class clx
{
   public abstract void f();
}

public class cly : clx
{
   public void f() // CS0114, hides base class member
   // try the following line instead
   // override public void f()
   {
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0115

'*function*' : no suitable method found to override

A method was marked as an override, but the compiler found no method to override.

The following sample generates CS0115:

```
// CS0115.cs
namespace x
{
   abstract public class clu
   {
      public abstract int f();
   }

   abstract public class clx
   {
      public override int f()   // CS0115
      {
         return 0;
      }

      public static void Main()
      {
      }
   }
}
```

You can resolve CS0115 in one of two ways:

- Remove the **override** keyword from the method in class `clx`.
- Use `clu` as a base class for `clx`.

Compiler Error CS0116

A namespace does not directly contain members such as fields or methods

Inside a namespace, the compiler only accepts classes, structs, unions, enums, interfaces, and delegates.

The following sample generates CS0116:

```
// CS0116.cs
namespace x
{
   int xx;   // CS0116
}
```

Compiler Error CS0117

'*type*' does not contain a definition for '*function*'

A call was made to a method that does not exist for the data type. This can also happen when a class name and its enclosing namespace name are the same and when a qualified method is called.

The following sample generates CS0117:

```
// CS0117_1.cs
namespace x
{
   public class a
   {
      public static void Main()
      {
         int i;
         i = i.get();   // CS0117, no get method on an int
      }
   }
}
```

When using indexers, it is not necessary to use the **Item** specifier:

```
// CS0117_2.cs
using System;
using System.Collections;

class Test
{
   public static void Main()
   {
      ArrayList al = new ArrayList();
      al.Add( new Test() );
      al.Add( new Test() );
      Console.WriteLine("First Element is {0}", al.Item[0]);   // CS0117
      // try the following line instead
      // Console.WriteLine("First Element is {0}", al[0]);
   }
}
```

Compiler Error CS0118

'*construct1_name*' denotes a '*construct1*' where a '*construct2*' was expected

The compiler detected what was probably the instantiation of a class; however, the data type was a namespace.

The following sample generates CS0118:

```
// CS0118.cs
namespace x
{
   class a
   {
      x ix = new x();   // CS0118, x not a class
      public static void Main()
      {
      }
   }
}
```

Compiler Error CS0119

'*construct1_name*' denotes a '*construct1*' which is not valid in the given context

The compiler detected an unexpected construct. For example:

- A class constructor is not a valid test expression in a conditional statement.
- A class name was used instead of an instance name to refer to an array element.

The following sample generates CS0119:

```
// CS0119.cs
namespace a
{
   public class z
   {
      public z()
      {
      }

      public static void Main()
      {
         (z()) ? 0 : 1;  // CS0119, cannot use constructor in a conditional statement
         // the following line is a more acceptable conditional statement
         // 1 < 2 ? 0 : 1;
      }
   }
}
```

Compiler Error CS0120

An object reference is required for the nonstatic field, method, or property '*member*'

In order to use a non-static field, method, or property, you must first create an object instance.

The following sample generates CS0120:

```
// CS0120_1.cs
public class MyClass
{
   // Non-static field
   public int i;
   // Non-static method
   public void f(){}
   // Non-static property
   int Prop
   {
      get
      {
         return 1;
      }
   }

   public static void Main()
   {
      i = 10;   // CS0120
      f();   // CS0120
      int p = Prop;   // CS0120
      // try the following lines instead
      // MyClass mc = new MyClass();
      // mc.i = 10;
      // mc.f();
      // int p = mc.Prop;
   }
}
```

CS0120 will also be generated if there is a call to a non-static method from a static method, as follows:

```
// CS0120_2.cs
// CS0120 expected
using System;

public class MyClass
{
   public static void Main()
   {
      TestCall();   // CS0120
      // To call a non-static method from Main,
      // first create an instance of the class.
      // Use the following two lines instead:
      // MyClass anInstanceofMyClass = new MyClass();
      // anInstanceofMyClass.TestCall();
   }

   public void TestCall()
   {
   }
}
```

Similarly, a static method cannot call an instance method unless you explicitly give it an instance of the class, as follows:

```
// CS0120_3.cs
using System;
```

```
public class MyClass
{
   public static void Main()
   {
      do_it("Hello There");   // CS0120
   }

   private void do_it(string sText)
   // You could also add the keyword static to the method definition:
   // private static void do_it(string sText)
   {
      Console.WriteLine(sText);
   }
}
```

Compiler Error CS0121

The call is ambiguous between the following methods or properties: '*method1*' and '*method2*'

Due to implicit conversion, the compiler was not able to call one form of an overloaded method. You can resolve this error in the following ways:

- Specify the method parameters in such a way that implicit conversion does not take place.
- Remove all overloads for the method.
- Cast to proper type before calling method.

The following sample generates CS0121:

```
// CS0121.cs
public class C
{
   void f(int i, double d)
   {
   }

   void f(double d, int i)
   {
   }

   public static void Main()
   {
      C c = new C();

      c.f(1, 1);   // CS0121
      // try the following line instead
      // c.f(1, 1.0);
      // or
      // c.f(1.0, 1);
      // or
      // c.f(1, (double)1);   // cast and specify which method to call
   }
}
```

Compiler Error CS0122

'*member*' is inaccessible due to its protection level

The access modifier for a class member prevents accessing the member.

The following sample generates CS0122:

```
// CS0122.cs
public class clx
{
   void f()   // make public to resolve CS0122
   {
   }
}

public class clz
{
   public static int Main()
   {
      clx a = new clx();
      a.f();   // CS0122, f is private
      return 0;
   }
}
```

Compiler Error CS0123

Method '*method*' does not match delegate '*delegate*'

An attempt to create a delegate failed because the correct signature was not used. Instances of a delegate must be declared with the same signature of the delegate declaration.

You can resolve this error by adjusting either your method or delegate signature.

The following sample generates CS0123:

```
// CS0123.cs
delegate void D();
// try the following line instead
// delegate void D(int i);

public class C
{
   public static void f(int i)
   {
   }

   public static void Main()
   {
      D d = new D(f);   // CS0123
   }
}
```

Compiler Error CS0126

An object of a type convertible to '*type*' required

A return statement is present, but the statement does not return a value of the expected type.

The following sample generates CS0126:

```
// CS0126.cs
public class a
{
   public int i
   {
      set
      {
      }
      get
      {
         return;   // CS0126, specify a value to return
      }
   }
}
```

Compiler Error CS0127

Since '*function*' returns void, a return keyword must not be followed by an object expression

A method with a void return type cannot return a value.

The following sample generates CS0127:

```
// CS0127.cs
namespace x
{
   public class b
   {
      public int hiddenMember2
      {
         get
         {
            return 0;
         }
         set   // CS0127, set has an implicit void return type
         {
            return 0;   // remove return statement to resolve this CS0127
         }
      }

      public static void Main()
      {
      }
   }
}
```

Compiler Error CS0128

A local variable named '*variable*' is already defined in this scope

The compiler detected declarations of two local variables with the same name.

The following sample generates CS0128:

```
// CS0128.cs
namespace x
{
   public class a
   {
      public static void Main()
      {
         char i;
         int i;   // CS0128
      }
   }
}
```

Compiler Error CS0131

The left-hand side of an assignment must be a variable, property or indexer

An assignment requires an l-value; check your syntax.

The following sample generates CS0131:

```
// CS0131.cs
public class MyClass
{
   public int i = 0;
   public void MyMethod()
   {
      i++ = 1;   // CS0131
      // try the following line instead
      // i = 1;
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0132

'*constructor*' : a static constructor must be parameterless

A static constructor cannot be declared with one or more parameters.

The following sample generates CS0132:

```
// CS0132.cs
namespace x
{
   public class clx
   {
      public clx(int i)
      {
      }
   }

   public class cly : clx
   {
      static cly(int i)   // CS0132
      {
      }
   }
}
```

Compiler Error CS0133

The expression being assigned to '*variable*' must be constant

A const variable cannot take as its value an expression that is not constant.

The following sample generates CS0133:

```
// CS0133.cs
public class A
{
   public const int i = c;   // CS0133, c is not constant
   public static int c = i;
   // try the following line instead
   // public const int i = 6;

   public static void Main()
   {
   }
}
```

Compiler Error CS0134

Cannot use qualified namespace names in nested namespace declarations

A qualified namespace is not permitted in a namespace declaration.

The following sample generates CS0134:

```
// CS0134.cs
namespace MyNameSpace
{
   namespace MyNameSpace.DottedNamespace   // CS0134, qualified namespace
   // try the following line instead
   // namespace NotRoot
   {
      public class MyClass
      {
         public static void Main()
         {
         }
      }

      namespace DottedNamespace
      {
         public class MyClass2
         {
            public static void f1()
            {
               MyNameSpace.NotRoot.MyClass.Main();   // legal use of qualified namespace
            }
         }
      }
   }
}
```

Compiler Error CS0135

'*declaration1*' conflicts with the declaration '*declaration2*'

The compiler does not allow hiding names, which commonly leads to logic errors in your code.

The following sample generates CS0135:

```
// CS0135.cs
public class MyClass2
{
   public static int i = 0;

   public static void Main()
   {
      {
         int i = 4;
         i++;
      }
      i = 0;   // CS0135
   }
}
```

Compiler Error CS0136

A local variable named '*var*' cannot be declared in this scope because it would give a different meaning to '*var*', which is already used in a 'parent or current' scope to denote something else

A variable declaration hides another declaration that would otherwise be in scope. Rename the variable that is declared on the line that generated CS0136.

The following sample generates CS0136:

```
// CS0136.cs
namespace x
{
   public class a
   {
      public static void Main()
      {
         int i = 0;
         {
            char i = 'a';   // CS0136, hides int i
         }
         i++;
      }
   }
}
```

Compiler Error CS0138

A using namespace directive can only be applied to namespaces; '*class*' is a class not a namespace

A using directive can only take the name of a namespace as a parameter.

The following sample generates CS0138:

```
// CS0138.cs
using System.Object;   // CS0138
```

Compiler Error CS0139

No enclosing loop out of which to break or continue

A break or continue statement was encountered outside of a loop.

For more information, see Jump Statements.

The following sample generates CS0139 twice:

```
// CS0139.cs
namespace x
{
   public class a
   {
      public static void Main()
      {
         continue;  // CS0139
         break;     // CS0139
      }
   }
}
```

Compiler Error CS0140

The label '*label*' is a duplicate

A label with the same name appeared twice.

The following sample generates CS0140:

```
// CS0140.cs
namespace x
{
   public class a
   {
      public static void Main()
      {
         l1: int i = 0;
         l1: int j = 0;   // CS0140, comment this line to resolve
         goto l1;
      }
   }
}
```

Compiler Error CS0143

The type '*class*' has no constructors defined

There is no appropriate constructor available.

The following sample generates CS0143:

```
// CS0143.cs
class nmc
{
   static public void Main ()
   {
      double d = new double(4.5);   // CS0143
   }
}
```

Compiler Error CS0144

Cannot create an instance of the abstract class or interface '*interface*'

You cannot create an instance of an abstract class or an interface.

The following sample generates CS0144:

```
// CS0144.cs
interface ii
{
}

public class a
{
   public static void Main()
   {
      ii xx = new ii();   // CS0144
   }
}
```

Compiler Error CS0145

A const field requires a value to be provided

You must initialize a const variable.

The following sample generates CS0145:

```
// CS0145.cs
class x
{
   const int i;   // CS0145
   // try the following line instead
   // const int i = 0;

   public static void Main()
   {
   }
}
```

Compiler Error CS0146

Circular base class definition between '*class1*' and '*class2*'

The inheritance list for a class includes a direct or indirect reference to itself. A class cannot inherit from itself.

The following sample generates CS0146:

```
// CS0146.cs
namespace x
{
   public interface a
   {
   }

   public class b : a, c
   {
      public void Main()
      {
      }
   }

   public class c : b   // CS0146
   {
   }
}
```

Compiler Error CS0148

The delegate '*delegate*' does not have a valid constructor

You imported and used a managed program (one that uses the .NET Framework common language runtime) that was created with another compiler. That compiler allowed an ill-formed delegate constructor.

Compiler Error CS0149

Method name expected

When creating a delegate, specify a method.

The following sample generates CS0149:

```
// CS0149.cs
using System;

delegate string func(int i);

class a
{
   static func dt;   // class member-field of the declared delegate type

   public static void Main()
   {
      dt = new func(17.45);   // CS0149
      // try the following line instead
      // dt = new func(func2);
      x(dt);
   }

   public static string func2(int j)
   {
      Console.WriteLine(j);
      return j.ToString();
   }

   public static void x(func myFunc)
   {
      myFunc(8);
   }
}
```

Compiler Error CS0150

A constant value is expected

A variable was found where a constant was expected.

The following sample generates CS0150:

```
// CS0150.cs
namespace x
{
   public class a
   {
      public static void Main()
      {
         int i = 0;
         int j = 0;

         switch(i)
         {
            case j:   // CS0150, j is a variable int, not a constant int
            // try the following line instead
            // case 1:
         }
      }
   }
}
```

Compiler Error CS0151

A value of an integral type expected

A variable was used in a situation where an integral data type was required. This can happen when there is no conversion or if the available implicit conversions result in an ambiguous situation.

The following sample generates CS0151:

```
// CS0151.cs
public class iii
{
   public static implicit operator int (iii aa)
   {
      return 0;
   }

   public static implicit operator long (iii aa)
   {
      return 0;
   }

   public static void Main()
   {
      iii a = new iii();

      switch (a)   // CS0151, compiler cannot choose between int and long
      // casting is one way to resolve this error
      // switch ((int)a)
      {
         case 1:
            break;
      }
   }
}
```

Compiler Error CS0152

The label '*label*' already occurs in this switch statement

A label was repeated in a switch statement.

The following sample generates CS0152:

```
// CS0152.cs
namespace x
{
   public class a
   {
      public static void Main()
      {
         int i = 0;

         switch (i)
         {
            case 1:
               i++;
               return;

            case 1:   // CS0152, two case 1 statements
               i++;
               return;
         }
      }
   }
}
```

Compiler Error CS0153

A goto case is only valid inside a switch statement

An attempt was made to use switch syntax outside of a **switch** statement.

The following sample generates CS0153:

```
// CS0153.cs
public class a
{
   public static void Main()
   {
      goto case 5;   // CS0153
   }
}
```

Compiler Error CS0154

The property or indexer '*property*' cannot be used in this context because it lacks the get accessor

An attempt to use a property failed because no get accessor method was defined in the property.

The following sample generates CS0154:

```
// CS0154.cs
public class b
{
   public int i
   {
      set
      {
      }
      // uncomment the get method to resolve this error
      /*
      get
      {
         return 0;
      }
      */
   }
}

public class a
{
   public static void Main()
   {
      b bb = new b();
      int j = bb.i;   // CS0154, no get method
   }
}
```

Compiler Error CS0155

The type caught or thrown must be derived from System.Exception

An attempt was made to pass a data type that does not derive from **System.Exception** into a catch block. Only data types that derive from **System.Exception** can be passed into a **catch** block.

For more information, see Exception Handling Statements.

The following sample generates CS0155:

```
// CS0155.cs
using System;

namespace x
{
   public class b
   // try the following line instead
   // public class b : Exception
   {
   }

   public class a
   {
      public static void Main()
      {
         try
         {
         }

         catch(b)   // CS0155, resolves if you derive b from Exception
         {
         }
      }
   }
}
```

Compiler Error CS0156

A throw statement with no arguments is not allowed outside of a catch clause

A throw statement with no parameters can only appear in a **catch** clause that takes no parameters.

For more information, see Exception Handling Statements.

The following sample generates CS0156:

```
// CS0156.cs
using System;

namespace x
{
   public class b : Exception
   {
   }

   public class a
   {
      public static void Main()
      {
         try
         {
            throw;   // CS0156
         }

         catch(b)
         {
            throw;   // this throw is valid
         }
      }
   }
}
```

Compiler Error CS0157

Control cannot leave the body of a finally clause

All of the statements in a finally clause must execute.

For more information, see Exception Handling Statements.

The following sample generates CS0157:

```
// CS0157.cs
using System;
namespace x
{
   public class b : Exception
   {
   }

   public class a
   {
      public static void Main()
      {
         try
         {
         }

         finally
         {
            return;   // CS0157, cannot leave finally clause
         }
      }
   }
}
```

Compiler Error CS0158

The label '*label*' shadows another label by the same name in a contained scope

A label in an inner scope hides a label with the same name in an outer scope.

The following sample generates CS0158:

```
// CS0158.cs
namespace x
{
   public class a
   {
      public static void Main()
      {
         goto lab1;
         lab1:
         {
            lab1:
            goto lab1;   // CS0158
         }
      }
   }
}
```

Compiler Error CS0159

No such label '*label*' within the scope of the goto statement

The label referenced by the goto statement could not be found within the scope of the **goto** statement.

The following sample generates CS0159:

```
// CS0159.cs
public class Class1
{
   public static void Main()
   {
      int i = 0;

      switch (i)
      {
         case 1:
            goto case 3;   // CS0159, case 3 label does not exist
         case 2:
            break;
      }
      goto NOWHERE;   // CS0159, NOWHERE label does not exist
   }
}
```

Compiler Error CS0160

A previous catch clause already catches all exceptions of this or a super type ('*type*')

A series of **catch** statements needs to be in decreasing order of derivation. For example, the most derived objects must appear first.

For more information, see Exception Handling Statements.

The following sample generates CS0160:

```
// CS0160.cs
using System;

public class b : Exception
{
}

public class Class1
{
   public static void Main()
   {
      try
      {
      }

      catch(Exception)   // Second-most derived; should be second catch
      {
      }

      catch(b)           // CS0160, Most derived; should be first catch
      {
      }

      catch              // Must be last catch
      {
      }
   }
}
```

Compiler Error CS0161

'*method*': not all code paths return a value

A method that returns a value must have a **return** statement in all code paths.

The following sample generates CS0161:

```
// CS0161.cs
public class Test
{
   public static int Main() // CS0161
   {
      int i = 10;
      if (i < 10)
      {
         return i;
      }
      else
      {
         // uncomment the following line to resolve
         // return 1;
      }
   }
}
```

Compiler Warning (level 2) CS0162

Unreachable code detected

The compiler detected code that will never be executed.

The following sample generates CS0162:

```
// CS0162.cs
// compile with: /W:2
public class A
{
   public static void Main()
   {
      goto lab1;
      {
         // The following statements cannot be reached:
         int i = 9;   // CS0162
         i++;
      }
      lab1:
      {
      }
   }
}
```

Compiler Error CS0163

Control cannot fall through from one case label ('*label*') to another

When a case statement contains one or more statements and is followed by another **case** statement, one of the following statements must explicitly terminate the **case**:

- **return**
- **goto**
- **break**

If you want to implement "fall through" behavior, use `goto case #`.

The following sample generates CS0163:

```
// CS0163.cs
public class MyClass
{
   public static void Main()
   {
      int i = 0;

      switch (i)   // CS0163
      {
         case 1:
            i++;
            // uncomment one of the following lines to resolve
            // return;
            // break;
            // goto case 3;

         case 2:
            i++;
            return;

         case 3:
            i = 0;
            return;
      }
   }
}
```

Compiler Warning (level 2) CS0164

This label has not been referenced

A label was declared but never used.

The following sample generates CS0164:

```
// CS0164.cs
// compile with: /W:2
public class a
{
   public int i = 0;

   public static void Main()
   {
      int i = 0;   // CS0164
      l1: i++;
      // the following lines resolve this error
      // if(i < 10)
      //    goto l1;
   }
}
```

Compiler Error CS0165

Use of unassigned local variable '*var*'

The C# compiler does not allow the use of uninitialized variables. If the compiler detects the use of a variable that might not have been initialized, it generates CS0165.

Use new to create an instance of an object or assign a value.

The following sample generates CS0165:

```
// CS0165.cs
using System;

class MyClass
{
   public int i;
}

class MyClass2
{
   public static void Main(string [] args)
   {
      int i, j;
      if (args[0] == "test")
      {
         i = 0;
      }

      /*
      // to resolve, either initialize the variables when declared
      // or provide for logic to initialize them, as follows:
      else
      {
         i = 1;
      }
      */

      j = i;   // CS0165, i might be uninitialized

      MyClass x;
      x.i = 0;   // CS0165
      // use new as follows
      // MyClass x = new MyClass();
      // x.i = 0;
   }
}
```

Compiler Error CS0167

The delegate '*delegate*' is missing the Invoke method

You imported and used a managed program (one that uses the .NET Framework common language runtime) that was created with another compiler. That compiler allowed an ill-formed delegate. Therefore, the **Invoke** method was not available.

Compiler Warning (level 3) CS0168

The variable '*var*' is declared but never used

The compiler warns when a variable is declared but not used.

The following sample generates two CS0168 warnings:

```
// CS0168.cs
// compile with: /W:3
public class clx
{
   public int i;
}

public class clz
{
   public static void Main()
   {
      int j = 0;   // CS0168, uncomment the following line
      // j++;
      clx a;       // CS0168, try the following line instead
      // clx a = new clx();
   }
}
```

Compiler Warning (level 3) CS0169

The private field '*class member*' is never used

A private variable was declared but never referenced. A common way to generate this warning is when you declare a private member of a class and do not use it.

The following sample generates CS0169:

```
// compile with: /W:3
using System;
public class ClassX
{
   int i;   // CS0169, i is not used anywhere

   public static void Main()
   {
   }
}
```

Compiler Error CS0170

Use of possibly unassigned field '*field*'

A field in a structure was used without first being initialized.

The following sample generates CS0170:

```
// CS0170.cs
public struct error
{
   public int i;
}

public class CmyClass
{
   public static void Main()
   {
      error e;
      // uncomment the next line to resolve this error
      // e.i = 0;
      System.Console.WriteLine( e.i );   // CS0170
   }
}
```

Compiler Error CS0171

Field '*field*' must be fully assigned before control leaves the constructor

A constructor in a struct must initialize all fields in the struct.

The following sample generates CS0171:

```
// CS0171.cs
struct MyStruct
{
   MyStruct(int initField)   // CS0171
   {
      // i = initField;      // uncomment this line to resolve this error
   }
   public int i;
}

class MyClass
{
   public static void Main()
   {
      MyStruct aStruct = new MyStruct();
   }
}
```

Compiler Error CS0172

Type of conditional expression can't be determined because '*type1*' and '*type2*' both implicitly convert to each other

In a conditional statement, you must be able to convert the types on either side of the `:` operator. Also, there cannot be mutual conversion routines; you only need one conversion.

The following sample generates CS0172:

```
// CS0172.cs
public class Square
{
   public class Circle
   {
      public static implicit operator Circle(Square aa)
      {
         return null;
      }

      public static implicit operator Square(Circle aa)
      // using explicit resolves this error
      // public static explicit operator Square(Circle aa)
      {
         return null;
      }
   }

   public static void Main()
   {
      Circle aa = new Circle();
      Square ii = new Square();
      object o = (1 == 1) ? aa : ii;   // CS0172
      // the following cast would resolve this error
      // (1 == 1) ? aa : (Circle)ii;
   }
}
```

Compiler Error CS0173

Type of conditional expression can't be determined because there is no implicit conversion between '*class1*' and '*class2*'

Conversions between classes are useful when you want objects of different classes to work with the same code. However, two classes that will work together cannot have mutual and redundant conversions.

To resolve CS0173, verify that there is one and only one implicit conversion between *class1* and *class2*, regardless of which direction the conversion is in and regardless of which class the conversion is in.

The following sample generates CS0173:

```
// CS0173.cs
// To resolve, mark three of the four conversion routines as explicit
// or remove three of the conversion routines.
public class iii
{
   // a conversion routine
   public static implicit operator a(iii aa)
   {
      return new a();
   }

   // a conversion routine
   public static implicit operator iii(a aa)
   {
      return new iii();
   }

   public static void Main()
   {
      a aa = new a();
      iii ii = new iii();
      a aaa = (1 == 1) ? aa : ii;   // CS0173
   }
}

public class a
{
   // a conversion routine
   public static implicit operator a(iii aa)
   {
      return new a();
   }

   // a conversion routine
   public static implicit operator iii(a aa)
   {
      return new iii();
   }
}
```

Compiler Error CS0174

A base class is required for a base reference

This error occurs only when the .NET Framework common language runtime compiles the source code for the **System.Object** class, which is the only class that has no base class.

Compiler Error CS0175

Use of keyword base is not valid in this context

The base keyword must be used to specify a particular member of the base class.

The following sample generates CS0175:

```
// CS0175.cs
using System;
class BaseClass
{
   public int TestInt = 0;
}

class MyClass : BaseClass
{
   public static void Main()
   {
      MyClass aClass = new MyClass();
      aClass.BaseTest();
   }

   public void BaseTest()
   {
      Console.WriteLine(base);   // CS0175
      // try the following line instead
      // Console.WriteLine(base.TestInt);
      base = 9;   // CS0175
      // try the following line instead
      // base.TestInt = 9;
   }
}
```

Compiler Error CS0176

Static member '*member*' cannot be accessed with an instance reference; qualify it with a type name instead

Only a class name can be used to qualify a static variable; an instance name cannot be a qualifier.

The following sample generates CS0176:

```
// CS0176.cs
public class b
{
   public static int ii;
}

public class a
{
   public static void Main()
   {
      b bb = new b();
      int i = bb.ii;   // CS0176
      // try the following line instead
      // int i = b.ii;
   }
}
```

Compiler Error CS0177

The out parameter '*parameter*' must be assigned to before control leaves the current method

A parameter marked with the out keyword was not assigned a value in the method body.

The following sample generates CS0177:

```
// CS0177.cs
public class iii
{
   public void f(out int i)   // CS0177
   {
   // uncomment the following line to resolve this error
   //   i = 0;
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0178

Incorrectly structured array initializer

An array initialization was ill-formed. When specifying the array dimensions, you can specify the following:

- A number in brackets
- Empty brackets
- A comma enclosed in brackets

The following sample generates CS0178:

```
// CS0178.cs
class x
{
   public static void Main()
   {
      a = new int[5][,][][5;   // CS0178, no comma or right bracket
   }
}
```

Compiler Error CS0179

'*member*' cannot be extern and declare a body

When a class member is marked extern, it means that the member's definition is located in another file. Therefore, a class member marked as **extern** cannot be defined in the class. Either remove the **extern** keyword or delete the definition.

The following sample generates CS0179:

```
// CS0179.cs
public class MyClass
{
   public extern int ExternMethod(int aa)   // CS0179
   {
      return 0;
   }
   // try the following line instead
   // public extern int ExternMethod(int aa);

   public static void Main()
   {
   }
}
```

Compiler Error CS0180

'*member*' cannot be both extern and abstract

The abstract and extern keywords are mutually exclusive. The **extern** keyword means that the member is defined outside the file, and **abstract** means that the implementation is provided in a derived class.

The following sample generates CS0180:

```
// CS0180.cs
namespace x
{
   public class iii
   {
      public extern abstract int aaa(int aa);   // CS0180

      public static void Main()
      {
      }
   }
}
```

Compiler Error CS0182

An attribute argument must be a constant expression, typeof expression or array creation expression

An argument to an attribute was not specified correctly.

The following sample generates CS0182:

```
// CS0182.cs
public class C
{
   static string s = "Test";

   [System.Diagnostics.ConditionalAttribute(s)]   // CS0182
   // try the following line instead
   // [System.Diagnostics.ConditionalAttribute("Test")]
   void nonConstantArgumentToConditional()
   {
   }

   public static void Main()
   {
   }
}
```

Compiler Warning (level 1) CS0183

The given expression is always of the provided ('*type*') type

If a conditional statement always evaluates to **true**, then you do not need a conditional statement.

The following sample generates CS0183:

```
// CS0183.cs
// compile with: /W:1
using System;
public class Test
{
   public static void Main()
   {
      Object obj3 = null;
      String str2 = "CS0183";
      obj3 = str2;

      if ( obj3 is String )
         Console.WriteLine( "obj3 is String" );

      if ( str2 is Object )   // CS0183
         Console.WriteLine( "str2 is Object" );
   }
}
```

Compiler Warning (level 1) CS0184

The given expression is never of the provided ('*type*') type

The expression can never be **true** because the variable you are testing is neither declared as ***type*** nor derived from ***type***.

The following sample generates CS0184:

```
// CS0184.cs
// compile with: /W:1
class MyClass
{
   public static void Main()
   {
      int i = 0;
      if (i is string)   // CS0184
         i++;
   }
}
```

Compiler Error CS0185

'*type*' is not a reference type as required by the lock statement

The lock statement can only evaluate reference types.

The following sample generates CS0185:

```
// CS0185.cs
public class MainClass
{
   public static void Main ()
   {
      lock (1)   // CS0185
      // try the following lines instead
      // MainClass x = new MainClass();
      // lock(x)
      {
      }
   }
}
```

Reference Types

Compiler Error CS0186

Use of null is not valid in this context

The following sample generates CS0186:

```
// CS0186.cs
using System;

class MyClass
{
   static void Main()
   {
      // Each of the following lines generates CS0186:
      if ((object)null is string) {}   // CS0186
      foreach (int i in null) {}   // CS0186
      string s = (object)null as string;   // CS0186
   }
}
```

Compiler Error CS0187

No such operator '*operator*' defined for type '*type*'

An operator was used on a type, but was not defined to do so.

The following sample generates CS0187:

```
// CS0187.cs
class MyClass
{
   public static void Main()
   {
      string someString = "Hello";
      someString++;   // CS0187
   }
}
```

Compiler Error CS0188

The this object cannot be used before all of its fields are assigned to

All fields in a struct have to be assigned by a constructor before the constructor can call a method in the struct.

The following sample generates CS0188:

```
// CS0188.cs
struct s
{
   public int a;

   void f()
   {
   }

   s (int i)
   {
      // a = i;
      f();  // CS0188
   }
}

class MyClass
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0191

A readonly field cannot be assigned to (except in a constructor or a variable initializer)

A readonly field can only take an assignment in a constructor or at declaration.

The following sample generates CS0191:

```
// CS0191.cs
class MyClass
{
   public readonly int TestInt = 6;  // OK to assign to readonly field in declaration

   MyClass()
   {
      TestInt = 11;                  // OK to assign to readonly field in constructor
   }

   public void TestReadOnly()
   {
      TestInt = 19;                  // CS0191
   }

   public static void Main()
   {
   }
}
```

CS0191 also results if the **readonly** field is static and the constructor is not marked **static**.

Compiler Error CS0192

A readonly field cannot be passed ref or out (except in a constructor)

A field (variable) marked with the readonly keyword cannot be passed either to a ref or out parameter except inside a constructor.

The following sample generates CS0192:

```
// CS0192.cs
class MyClass
{
   public readonly int TestInt = 6;

   static void TestMethod(ref int testInt)
   {
      testInt = 0;
   }

   MyClass()
   {
      TestMethod(ref TestInt);   // OK
   }

   public void PassReadOnlyRef()
   {
      TestMethod(ref TestInt);   // CS0192
   }

   public static void Main()
   {
   }
}
```

CS0192 also results if the **readonly** field is static and the constructor is not marked **static**.

Compiler Error CS0193

The * or -> operator must be applied to a pointer

The ***** or **->** operator was used with a nonpointer type.

The following sample generates CS0193:

```
// CS0193.cs
using System;

public struct Age
{
   public int AgeYears;
   public int AgeMonths;
   public int AgeDays;
}

public class MyClass
{
   public static void SetAge(ref Age anAge, int years, int months, int days)
   {
      anAge->Months = 3;   // CS0193, anAge is not a pointer
      // try the following line instead
      // anAge.AgeMonths = 3;
   }

   public static void Main()
   {
      Age MyAge = new Age();
      Console.WriteLine(MyAge.AgeMonths);
      SetAge(ref MyAge, 22, 4, 15);
      Console.WriteLine(MyAge.AgeMonths);
   }
}
```

Compiler Error CS0196

A pointer must be indexed by only one value

A pointer cannot have multiple indices.

The following sample generates CS0196:

```
// CS0196.cs
public class MainClass
{
   public static void Main ()
   {
      int *i = null;
      int j = 0;
      j = i[1,2];   // CS0196
      // try the following line instead
      // j = i[1];
   }
}
```

Compiler Error CS0197

Cannot pass '*argument*' as ref or out, because ' *argument* ' is a marshal-by-reference class

Any class that derives (directly or indirectly) from **System.MarshalByRefObject** is a "marshal-by-reference" class. Such a class can be marshaled by reference across process and machine boundaries. Thus, instances of this class could be proxies to remote objects. You cannot pass a field of a proxy object as ref or out. So, you cannot pass fields of such a class as **ref** or **out**, unless the instance is this, which can never be a proxy object.

The following sample generates CS0197:

```
// CS0197a.cs
using System;
class X : MarshalByRefObject
{
   public int i;
}

class M
{
   public int i;
   static void AddSeventeen(ref int i)
   {
      i += 17;
   }

   static void Main()
   {
      X x = new X();
      x.i = 12;
      AddSeventeen(ref x.i);   // CS0197
      // try the following lines instead
      // M m = new M();
      // m.i = 12;
      // AddSeventeen(ref m.i);
   }
}
```

The following sample generates CS0197 when you try to pass the structure **System.Drawing.Point** as a reference:

```
// CS0197b.cs
public class A : System.MarshalByRefObject
{
   public System.Drawing.Point point;
}

public class B
{
   public void Notify()
   {
      A a = new A();
      if ( !a.point.IsEmpty )   // CS0197
      // try the following line instead
      // if(!((System.Drawing.Point)((object)(a.point))).IsEmpty)
         {
         }
   }
   static void Main()
   {
   }
}
```

Compiler Error CS0198

A static readonly field cannot be assigned to (except in a static constructor or a variable initializer)

A readonly variable must have the same static usage as the constructor in which you want to initialize it.

The following sample generates CS0198:

```
// CS0198.cs
class MyClass
{
   public static readonly int TestInt = 6;

   MyClass()
   {
      TestInt = 11;   // CS0198, constructor is not static and readonly field is
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0199

A static readonly field cannot be passed ref or out (except in a static constructor)

A readonly variable must have the same static usage as the constructor in which you want to pass it as a ref or out parameter.

The following sample generates CS0199:

```
// CS0199.cs
class MyClass
{
   public static readonly int TestInt = 6;

   static void TestMethod(ref int testInt)
   {
      testInt = 0;
   }

   MyClass()
   {
      TestMethod(ref TestInt);   // CS0199, TestInt is static
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0200

Property or indexer '*property*' cannot be assigned to — it is read only

An attempt was made to assign a value to a property, but the property does not have a set accessor. Resolve the error by adding a set accessor.

The following sample generates CS0200:

```
// CS0200.cs
public class MainClass
{
   // private int _mi;
   int I
   {
      get
      {
         return 1;
      }

      // uncomment the set accessor and declaration for _mi
      /*
      set
      {
         _mi = value;
      }
      */
   }

   public static void Main ()
   {
      MainClass II = new MainClass();
      II.I = 9;   // CS0200
   }
}
```

Compiler Error CS0201

Only assignment, call, increment, decrement, and new object expressions can be used as a statement

The compiler generates an error when it encounters a meaningless statement.

The following sample generates CS0201:

```
// CS0201.cs
using System;

public class MainClass
{
   public static void Main ()
   {
      2 * 3;   // CS0201
   }
}
```

Compiler Error CS0202

The call to GetEnumerator must return a class or a struct, not '*type*'

A call to **GetEnumerator** cannot return a pointer; it must return an instance.

The following sample generates CS0202:

```
// CS0202.cs
// compile with: /unsafe

public class C1
{
   public int Current
   {
      get
      {
         return 0;
      }
   }

   public bool MoveNext ()
   {
      return false;
   }

   public static implicit operator C1 (int c1)
   {
      return 0;
   }
}

public class C2
{
   public int Current
   {
      get
      {
         return 0;
      }
   }

   public bool MoveNext ()
   {
      return false;
   }

   public C1* GetEnumerator ()
   // try the following line instead
   // public C1 GetEnumerator ()
   {
      return null;
   }
}

public class MainClass
{
   unsafe public static void Main ()
   {
      C2 c2 = new C2();

      foreach (C1 x in c2)   // CS0202
      {
         System.Console.WriteLine(x.Current);
      }
   }
}
```

Compiler Error CS0204

Only 65535 locals are allowed

The limit of 65535 local variables has been exceeded in a method.

Compiler Error CS0205

Cannot call an abstract base member: '*method*'

You cannot call an abstract method, even from within the implementation of the method.

The following sample generates CS0205:

```
// CS0205.cs
abstract public class MyClass
{
   abstract public void mf();
}

public class MyClass2 : MyClass
{
   public override void mf()
   {
      base.mf();   // CS0205, delete this line
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0206

A property or indexer may not be passed as an out or ref parameter

A property is not available to be passed as a ref or out parameter.

The following sample generates CS0206:

```
// CS0206.cs
public class MyClass
{
   public static int iii
   {
      get
      {
         return 0;
      }
      set
      {
      }
   }

   public static void MyMeth(ref int i)
   // public static void MyMeth(int i)
   {
   }

   public static void Main()
   {
      MyMeth(ref iii);   // CS0206
      // try the following line instead
      // MyMeth(iii);   // CS0206
   }
}
```

Compiler Error CS0208

Cannot take the address or size of a variable of a managed type ('S')

Even when used with the unsafe keyword, taking the address of a managed object is not allowed. For more information on managed objects, see A.2 Pointer types.

The following sample generates CS0208:

```
// CS0208.cs
// compile with: /unsafe

class S
{
   public int a = 98;
}

public class a
{
   unsafe public static int Main()
   {
      S s = new S();  // S is managed
      S * s2 = &s;    // CS0208
      return 1;
   }
}
```

Compiler Error CS0209

The type of locals declared in a fixed statement must be a pointer type

The variable that you declare in a fixed statement must be a pointer.

The following sample generates CS0209:

```
// CS0209.cs
// compile with: /unsafe

class Point
{
   public int x, y;
}

public class Class
{
   unsafe public static void Main()
   {
      Point pt = new Point();

      fixed (int i)    // CS0209
      {
      }
      // try the following lines instead
      /*
      fixed (int* p = &pt.x)
      {
      }
      fixed (int* q = &pt.y)
      {
      }
      */
   }
}
```

Compiler Error CS0210

You must provide an initializer in a fixed or using statement declaration

You must declare and initialize the variable in a fixed statement.

The following sample generates CS0210:

```
// CS0210a.cs
// compile with: /unsafe

class Point
{
   public int x, y;
}

public class Class
{
   unsafe public static void Main()
   {
      Point pt = new Point();

      fixed (int i)    // CS0210
      {
      }
      // try the following lines instead
      /*
      fixed (int* p = &pt.x)
      {
      }
      fixed (int* q = &pt.y)
      {
      }
      */
   }
}
```

The following sample also generates CS0210 because the using statement has no initializer.

```
// CS0210b.cs

using System.IO;
class Test
{
   static void Main()
   {
      using (StreamWriter w) // CS0210
      // Try this line instead:
      // using (StreamWriter w = new StreamWriter("TestFile.txt"))
      {
         w.WriteLine("Hello there");
      }
   }
}
```

Compiler Error CS0211

Cannot take the address of the given expression

You can take the address of fields, local variables, and indirection of pointers, but you cannot take, for example, the address of the sum of two local variables.

The following sample generates CS0211:

```
// CS0211.cs
// compile with: /unsafe

public class a
{
   unsafe public void mf()
   {
      int a = 0, b = 0;
      int *i = &(a + b);   // CS0211, the addition of two local variables
      // try the following line instead
      // int *i = &a;
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0212

You can only take the address of unfixed expression inside of a fixed statement initializer

The following sample generates CS0212 and shows how to take the address of an unfixed expression:

```
// CS0212a.cs
// compile with: /unsafe

public class A {
    public int iField = 5;

    unsafe public void mf() {
        A a = new A();
        int* ptr = &a.iField;   // CS0212

        // Try the following code instead:
        /*
        fixed (int* ptr = &a.iField)
        {
        }
        */
    }
    static void Main()
    {
    }
}
```

The following sample also generates CS0212 and shows how to resolve the error:

```
// CS0212b.cs
// compile with: /unsafe
using System;

public class MyClass
{
   unsafe public void mf()
   {
      // Null-terminated ASCII characters in an sbyte array
      sbyte[] sbArr1 = new sbyte[] { 0x41, 0x42, 0x43, 0x00 };
      sbyte* pAsciiUpper = &sbArr1[0];   // CS0212
      // To resolve this error, delete the previous line and
      // uncomment the following code:
      // fixed (sbyte* pAsciiUpper = sbArr1)
      // {
      //    String szAsciiUpper = new String(pAsciiUpper);
      // }
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0213

You do not need to use the fixed statement to take the address of an already fixed expression

A local variable in an unsafe method or a parameter is already fixed (on the stack), so you cannot take the address of either of these two variables in a fixed expression.

The following sample generates CS0213:

```
// CS0213.cs
// compile with: /unsafe
public class MyClass
{
   unsafe public static void Main()
   {
      int i = 45;
      fixed (int *j = &i)   // CS0213
      {
      }

      // try the following line instead
      // int* j = &i;
   }
}
```

Compiler Error CS0214

Pointers may only be used in an unsafe context

Pointers can only be used with the unsafe keyword.

The following sample generates CS0214:

```
// CS0214.cs
public struct S
{
   public int a;
}

public class a
{
   public static int Main()
   // try the following line instead
   // unsafe public static int Main()
   {
      S s = new S();
      S * s2 = &s;    // CS0214
      s2->a = 3;      // CS0214

      return 1;
   }
}
```

Compiler Error CS0215

The return type of operator True or False must be bool

User-defined true and false operators must have a return type of bool.

The following sample generates CS0215:

```
// CS0215.cs
class MyClass
{
   public static int operator true (MyClass MyInt)   // CS0215
   // try the following line instead
   // public static bool operator true (MyClass MyInt)
   {
      return true;
   }

   public static int operator false (MyClass MyInt)   // CS0215
   // try the following line instead
   // public static bool operator false (MyClass MyInt)
   {
      return true;
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0216

The operator '*operator*' requires a matching operator '*missing_operator*' to also be defined

A user-defined true operator requires a user-defined false operator, and vice versa.

The following sample generates CS0216:

```
// CS0216.cs
class MyClass
{
   public static bool operator true (MyClass MyInt)   // CS0216
   {
      return true;
   }

   // to resolve, uncomment the following operator definition
   /*
   public static bool operator false (MyClass MyInt)
   {
      return true;
   }
   */

   public static void Main()
   {
   }
}
```

Compiler Error CS0217

In order to be applicable as a short circuit operator a user-defined logical operator ('*operator*') must have the same return type as the type of its 2 parameters.

If you define an operator for a user-defined type, and then try to use the operator as a short-circuit operator, the user-defined operator must have parameters and return values of the same type. For more information on short-circuit operators, see && Operator and || Operator.

The following sample generates CS0217:

```
// CS0217.cs
using System;

public class MyClass
{
   public static bool operator true (MyClass f)
   {
      return false;
   }

   public static bool operator false (MyClass f)
   {
      return false;
   }

   public static implicit operator int(MyClass x)
   {
      return 0;
   }

   public static int operator & (MyClass f1, MyClass f2)   // CS0217
   // try the following line instead
   // public static MyClass operator & (MyClass f1, MyClass f2)
   {
      return new MyClass();
   }

   public static void Main()
   {
      MyClass f = new MyClass();
      int i = f && f;
   }
}
```

Compiler Error CS0218

The type ('*type*') must contain declarations of operator true and operator false

If you define an operator for a user-defined type, and then try to use the operator as a short-circuit operator, the user-defined operator must have operator true and operator false defined. For more information on short-circuit operators, see && Operator and || Operator.

The following sample generates CS0218:

```
// CS0218.cs
using System;
public class MyClass
{
   // uncomment these operator declarations to resolve this CS0218
   /*
   public static bool operator true (MyClass f)
   {
      return false;
   }

   public static bool operator false (MyClass f)
   {
      return false;
   }
   */

   public static implicit operator int(MyClass x)
   {
      return 0;
   }

   public static MyClass operator & (MyClass f1, MyClass f2)
   {
      return new MyClass();
   }

   public static void Main()
   {
      MyClass f = new MyClass();
      int i = f && f;   // CS0218, requires operators true and false
   }
}
```

Compiler Warning (level 3) CS0219

The variable '*variable*' is assigned but never used

The variable '*variable*' is assigned but its value is never used

The compiler issues a level-three warning, when you declare and assign a variable, but do not use it.

The following sample generates CS0219:

```
// CS0219.cs
// compile with: /W:3
public class MyClass
{
   public static void Main()
   {
      int a = 0;   // CS0219
   }
}
```

Compiler Error CS0220

The operation overflows at compile time in checked mode

An operation was detected by checked, which is the default, and a data loss resulted. Either correct the inputs to the assignment or use unchecked to resolve this error.

The following sample generates CS0220:

```
// CS0220.cs
using System;

class TestClass
{
   const int x = 1000000;
   const int y = 1000000;

   public int MethodCh()
   {
      int z = (x * y);   // CS0220
      return z;
   }

   public int MethodUnCh()
   {
      unchecked
      {
         int z = (x * y);
         return z;
      }
   }

   public static void Main()
   {
      TestClass myObject = new TestClass();
      Console.WriteLine("Checked  : {0}", myObject.MethodCh());
      Console.WriteLine("Unchecked: {0}", myObject.MethodUnCh());
   }
}
```

Compiler Error CS0221

Constant value '*value*' cannot be converted to a '*type*' (use 'unchecked' syntax to override)

An assignment operation that would result in a data loss was detected by checked, which is on by default. Either correct the assignment or use unchecked to resolve this error.

The following sample generates CS0221:

```
// CS0221.cs
public class MyClass
{
   public static void Main()
   {
      // unchecked
      // {
         int a = (int)0xFFFFFFFF;   // CS0221
         a++;
      // }
   }
}
```

Compiler Error CS0225

The params parameter must be a single dimensional array

When using the params keyword, you must specify a single-dimensional array of the data type.

The following sample generates CS0225:

```
// CS0225.cs
public class MyClass
{
   public static void TestParams(params int a)   // CS0225
   // try the following line instead
   // public static void TestParams(params int[] a)
   {
   }

   public static void Main()
   {
      TestParams(1);
   }
}
```

Compiler Error CS0227

Unsafe code may only appear if compiling with /unsafe

If source code contains the unsafe keyword, then the /unsafe compiler option must also be used.

The following sample, when compiled without **/unsafe**, will generate CS0227:

```
// CS0227.cs
public class a
{
   unsafe public static void Main()   // CS0227
   {
   }
}
```

Compiler Error CS0228

'*type*' does not contain a definition for '*member*', or it is not accessible

You may have replaced the system version of **System.Hashtable**, **System.String**, or **System.Array**, and the replacement does not contain *member*.

Otherwise, you may need to reinstall Visual Studio.

Compiler Error CS0229

Ambiguity between '*member1*' and '*member2*'

Members of different interfaces have the same name. If you want to keep the same names, you must qualify the names.

The following sample generates CS0229:

```
// CS0229.cs
interface IList
{
   int Count
   {
      get;
      set;
   }
}

interface Icounter
{
   void Count(int i);
}

interface IListCounter : IList , Icounter
{
}

class main
{
   void Test(IListCounter x)
   {
      x.Count = 1;  // CS0229
      x.Count(1);   // CS0229
      // try the following lines instead
      // ((IList)x).Count = 1;
      // ((ICounter)x).Count(1);
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0230

Type and identifier are both required in a foreach statement

A foreach statement was poorly formed.

The following sample generates CS0230:

```
// CS0230.cs
using System;

class MyClass
{
   public static void Main()
   {
      int[] myarray = new int[3] {1,2,3};

      foreach (int in myarray)   // CS0230
      // try the following line instead
      // foreach (int x in myarray)
      {
         Console.WriteLine(x);
      }
   }
}
```

Compiler Error CS0231

A params parameter must be the last parameter in a formal parameter list.

The following sample generates CS0231:

```
// CS0231.cs
class Test
{
   public void TestMethod(params int[] p, int i) {} // CS0231
   // To resolve the error, use the following line instead:
   // public void TestMethod(int i, params int[] p) {}

   static void Main()
   {
   }
}
```

Compiler Error CS0233

sizeof can only be used in an unsafe context (consider using System.Runtime.InteropServices.Marshal.SizeOf)

The sizeof operator can only be used in an unsafe block.

The following sample generates CS0233:

```
// CS0233.cs
using System;
using System.Runtime.InteropServices;

[StructLayout(LayoutKind.Sequential)]
public struct S
{
   public int a;
}

public class MyClass
{
   public static void Main()
   {
      S myS = new S();
      Console.WriteLine(sizeof(myS));   // CS0233
      // try the following line instead
      // Console.WriteLine(Marshal.SizeOf(myS));
   }
}
```

Compiler Error CS0234

The type or namespace name '*name*' does not exist in the class or namespace '*scope*' (are you missing an assembly reference?)

A type was expected. Possible reasons include:

- An assembly that contains the definition of a type was not referenced in the compilation; use /reference (Import Metadata) to specify the assembly.
- You passed a variable name to the typeof operator.

See Add Reference Dialog Box for information on how to add a reference in the development environment.

The following sample generates CS0234:

```
// CS0234.cs
public class C
{
   public static void Main()
   {
      System.DateTime x = new System.DateTim();   // CS0234
      // try the following line instead
      // System.DateTime x = new System.DateTime();
   }
}
```

Compiler Error CS0236

A field initializer cannot reference the nonstatic field, method, or property '*field*'

Instance fields cannot be used to initialize other instance fields outside of a method.

The following sample generates CS0236:

```
// CS0236.cs
public class MyClass
{
   public int i = 5;
   public int j = i;  // CS0236
   public int k;      // initialize in constructor

   MyClass()
   {
      k = i;
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0238

'*member*' cannot be sealed because it is not an override

sealed was used on a member that was not also marked with override.

The following sample generates CS0238:

```
// CS0238.cs
abstract class cly
{
   public abstract void f();
}

class clx : cly
{
   public static void Main()
   {
   }

   public sealed void f() // CS0238
   // Try the following definition instead:
   // public override sealed void f()
   {
   }
}
```

Compiler Error CS0239

'*member*' : cannot override inherited member '*inherited member*' because it is sealed

A member cannot override a sealed inherited member.

The following sample generates CS0239:

```
// CS0239.cs
abstract class cly
{
   public abstract void f();
}

class clx : cly
{
   public static void Main()
   {
   }

   public override sealed void f()
   {
   }
}

class clz : clx
{
   public override void f()   // CS0239
   // Try the following definition instead:
   // public new void f()
   {
   }
}
```

Compiler Error CS0241

Default parameter specifiers are not permitted

Method parameters cannot have default values. Use method overloads if you want to achieve the same effect.

The following sample generates CS0241:

```
// CS0241.cs
public class TestClass
{
   public void TestMethod(int i = 9)   // CS0241
   // try the following line instead
   // public void TestMethod(int i)
   {
   }

   public static void Main()
   {
      TestClass x = new TestClass();
      x.TestMethod(9);
   }
}
```

Compiler Error CS0242

The operation in question is undefined on void pointers

Incrementing a void pointer is not allowed.

The following sample generates CS0242:

```
// CS0242.cs
// compile with: /unsafe
class TestClass
{
   public unsafe void Test()
   {
      void * p = null;
      p++;   // CS0242, incrementing a void pointer not allowed
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0243

Conditional not valid on '*method*' because it is an override method

The Conditional attribute is not allowed on a method that is marked with the override keyword.

The compiler never binds to override methods; it only binds to the base method and the common language runtime calls the override, as appropriate.

The following sample generates CS0243:

```
// CS0243.cs
public class MyClass
{
   public virtual void M()
   {
   }
}

public class MyClass2 : MyClass
{
   [System.Diagnostics.ConditionalAttribute("MySymbol")]   // CS0243
   // remove Conditional attribute or remove override keyword
   public override void M()
   {
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0244

"is" or "as" are not valid on pointer types

The is and as keywords are not valid for use on pointer types.

The following sample generates CS0244:

```
// CS0244.cs
// compile with: /unsafe
using System;

class UnsafeTest
{
   unsafe static void SquarePtrParam (int* p)
   {
      bool b = p is object;   // CS0244, p is pointer
   }

   unsafe public static void Main()
   {
      int i = 5;
      SquarePtrParam (&i);
   }
}
```

Compiler Error CS0245

Destructors and object.Finalize cannot be called directly. Consider calling IDisposable.Dispose if available.

For more information, see Programming Essentials for Garbage Collection.

The following sample generates CS0245:

```
// CS0245.cs
using System;
using System.Collections;

class C // : IDisposable
{
   /*
   public void Dispose()
   {
      // cleanup code goes here
   }
   */

   void m()
   {
      this.Finalize();   // CS0245
      // this.Dispose();
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0246

The type or namespace name '*type/namespace*' could not be found (are you missing a using directive or an assembly reference?)

A type was not found. You may have forgotten to reference (/reference) the assembly that contains the type or you may not have correctly qualified its use with the using directive.

There are several reasons for this error:

1. The name of the type or namespace you are trying to use may be misspelled (including the correct case). Without the correct name the compiler is unable to find the definition for the type or namespace you have referred to in your code. This occurs most often because C# is case-sensitive and the correct casing has not been used when referring to the type. For example, `Dataset ds;` will generate CS0246; notice the s in Dataset is not capitalized.
2. If the error is for a namespace name, you may not have referenced (/reference) the assembly containing the namespace. For example, your code might contain `using Accessibility;`. However, if your project doesn't reference the assembly Accessibility.dll then you will get CS0246. See the Add Reference Dialog Box for information on how to reference an assembly in the development environment.

   See Add Reference Dialog Box for information on how to add a reference in the development environment.

3. If the error is for a type name, you may not have the proper using directive, or you have not fully qualified the name of the type. Consider the following line of code: `DataSet ds;`. To be able to use the DataSet type you would need to do two things. First, you need a reference to the assembly that contains the definition for the DataSet type. Second, you need a using directive for the namespace where DataSet is located. For example, because DataSet is located in the **System.Data** namespace, you would need the following statement at the beginning of your code: `using System.Data;`.

   The second step is not required. However, if you omitted this step then it would require that you fully qualify the DataSet type when referring to it. Fully qualifying it means that you use the namespace and type each time you refer to it in your code. So, if you decided to skip the second step you would need to change your declaration code above to: `System.Data.DataSet ds;`.

The following sample generates CS0246:

```
// CS0246.cs
// using System.Diagnostics;

public class MyClass
{
   [Conditional("A")]   // CS0246, uncomment using directive to resolve
   public void Test()
   {
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0247

Cannot use a negative size with stackalloc

A negative number was passed to a stackalloc statement.

The following sample generates CS0247:

```
// CS0247.cs
// compile with: /unsafe
public class MyClass
{
   unsafe public static void Main()
   {
      int *p = stackalloc int [-30];   // CS0247
   }
}
```

Compiler Error CS0248

Cannot create an array with a negative size

An array size was specified with a negative number.

The following sample generates CS0248:

```
// CS0248.cs
class MyClass
{
   public static void Main()
   {
      int[] myarray = new int[-3] {1,2,3};   // CS0248, pass a nonnegative number
   }
}
```

Compiler Error CS0249

Do not override object.Finalize. Instead, provide a destructor.

Use destructor syntax to specify instructions to execute when your object is destroyed.

See Using C# and Managed Extensions for C++ Destructor Syntax for more information.

The following sample generates CS0249:

```
// CS0249.cs
class C
{
   protected override void Finalize()   // CS0249
   // try the following line instead
   // ~C()
   {
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0250

Do not directly call your base class Finalize method. It is called automatically from your destructor.

A program cannot attempt to force cleanup of base class resources.

See Finalize Methods and Destructors for more information.

The following sample generates CS0250

```
// CS0250.cs
class B
{
}

class C : B
{
   ~C()
   {
      base.Finalize();   // CS0250
   }

   public static void Main()
   {
   }
}
```

Compiler Warning (level 2) CS0251

Indexing an array with a negative index (array indices always start at zero)

Do not use a negative number to index into an array.

The following sample generates CS0251:

```
// CS0251.cs
// compile with: /W:2
class MyClass
{
   public static void Main()
   {
      int[] myarray = new int[] {1,2,3};
      try
      {
         myarray[-1]++;   // CS0251
         // try the following line instead
         // myarray[1]++;
      }
      catch (System.IndexOutOfRangeException e)
      {
         System.Console.WriteLine("{0}", e);
      }
   }
}
```

Compiler Warning (level 2) CS0252

Possible unintended reference comparison; to get a value comparison, cast the left hand side to type '*type*'

The compiler is doing a reference comparison. If you want to compare the value of strings, cast the left side of the expression to *type*.

The following sample generates CS0252:

```
// CS0252.cs
// compile with: /W:2
using System;

class MyClass
{
   public static void Main()
   {
      string s = "11";
      object o = s + s;

      bool b = o == s;   // CS0252
      // try the following line instead
      // bool b = (string)o == s;
   }
}
```

Compiler Warning (level 2) CS0253

Possible unintended reference comparison; to get a value comparison, cast the right hand side to type '*type*'

The compiler is doing a reference comparison. If you want to compare the value of strings, cast the right side of the expression to *type*.

The following sample generates CS0253:

```
// CS0253.cs
// compile with: /W:2
using System;
class MyClass
{
   public static void Main()
   {
      string s = "11";
      object o = s + s;

      bool c = s == o;   // CS0253
      // try the following line instead
      // bool c = s == (string)o;
   }
}
```

Compiler Error CS0254

The right hand side of a fixed statement assignment may not be a cast expression

The right side of a fixed expression may not use a cast.

The following sample generates CS0254:

```
// CS0254.cs
// compile with: /unsafe
class Point
{
   public int x, y;
}

class FixedTest
{
   unsafe static void SquarePtrParam (int* p)
   {
      *p *= *p;
   }

   unsafe public static void Main()
   {
      Point pt = new Point();
      pt.x = 5;
      pt.y = 6;

      fixed (int* p = (int)&pt.x)   // CS0254
      // try the following line instead
      // fixed (int* p = &pt.x)
      {
         SquarePtrParam (p);
      }
   }
}
```

Compiler Error CS0255

stackalloc may not be used in a catch or finally block

The stackalloc keyword may not be used in a catch or finally block.

The following sample generates CS0255:

```
// CS0255.cs
// compile with: /unsafe
using System;

public class TestTryFinally
{
   public static unsafe void Test()
   {
      int i = 123;
      string s = "Some string";
      object o = s;

      try
      {
         // Conversion is not valid; o contains a string not an int
         i = (int) o;
      }

      finally
      {
         Console.Write("i = {0}", i);
         int* fib = stackalloc int[100];   // CS0255
      }
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0500

'*class member*' cannot declare a body because it is marked abstract

An abstract method cannot contain its implementation.

The following sample generates CS0500:

```
// CS0500.cs
namespace x
{
   abstract public class clx
   {
      abstract public void f(){}   // CS0500
      // try the following line instead
      // abstract public void f();
   }

   public class cly
   {
      public static int Main()
      {
         return 0;
      }
   }
}
```

Compiler Error CS0501

'*member function*' must declare a body because it is not marked abstract or extern

Nonabstract methods must have implementations. For example, the following sample generates CS0501:

```
// CS0501.cs
namespace x
{
   public class clx
   {
      public void f();   // CS0501, needs implementation
   }
}
```

Compiler Error CS0502

The class '*class*' is abstract and sealed

A class cannot be both abstract and sealed.

The following sample generates CS0502:

```
// CS0502.cs
namespace x
{
   abstract sealed public class clx   // CS0502
   {
      abstract public void f();
   }
}
```

Compiler Error CS0503

The abstract method '*method*' cannot be marked virtual

It is redundant to mark a member method as both abstract and virtual because **abstract** implies **virtual**.

The following sample generates CS0503:

```
// CS0503.cs
namespace x
{
   abstract public class clx
   {
      abstract virtual public void f();   // CS0503
   }
}
```

Compiler Error CS0504

The constant '*variable*' cannot be marked static

If a variable is const, it is also static. If you want a **const** and **static** variable, just declare that variable as **const**; if all you want is a **static** variable, just mark it **static**.

The following sample generates CS0504:

```
// CS0504.cs
namespace x
{
   abstract public class clx
   {
      static const int i = 0;   // CS0504, cannot be both static and const
      abstract public void f();
   }
}
```

Compiler Error CS0505

'*member1*' : cannot override; '*member2*' is not a function

A class declaration attempted to override a non-method in a base class. Overrides must match the member type. If a method with the same name as a method in a base class is desired, use new (and not override) on the method declaration in the base class.

The following sample generates CS0505:

```
// CS0505.cs
namespace x
{
   public class clx
   {
      public int i;

      int z()
      {
         return 0;
      }
   }

   public class cly : clx
   {
      public override int i() // CS0505, clx::i is a variable
      {
         return 0;
      }

      public static void Main()
      {
      }
   }
}
```

Compiler Error CS0506

'*function1*' : cannot override inherited member '*function2*' because it is not marked "virtual", "abstract", or "override"

A method was overridden that was not explicitly marked as **virtual**, **abstract**, or **override**.

The following sample generates CS0506:

```
// CS0506.cs
namespace MyNameSpace
{
   abstract public class ClassX
   {
      public int i = 0;

      public int f()
      {
         return 0;
      }
      // Try the following definition for f() instead:
      // abstract public int f();
   }

   public class ClassY : ClassX
   {
      public override int f()   // CS0506
      {
         return 0;
      }

      public static int Main()
      {
         return 0;
      }
   }
}
```

Compiler Error CS0507

'*function1*' : cannot change access modifiers when overriding '*access*' inherited member '*function2*'

An attempt was made to change the access specification in a method override.

The following sample generates CS0507:

```
// CS0507.cs
abstract public class clx
{
   public int i = 0;

   virtual protected int f()
   {
      return 0;
   }
}

public class cly : clx
{
   public override int f()   // CS0507
   {
      return 0;
   }

   public static int Main()
   {
      return 0;
   }
}
```

Compiler Error CS0508

'*function1*' cannot change return type when overriding inherited member '*function2*'

An attempt was made to change the return type in a method override.

The following sample generates CS0508:

```
// CS0508.cs
namespace x
{
   abstract public class clx
   {
      public int i = 0;
      abstract public int f();   // return type is int
   }

   public class cly : clx
   {
      public override double f()
      {
         return 0.0;             // CS0508
      }

      public static int Main()
      {
         return 0;
      }
   }
}
```

Compiler Error CS0509

'*class1*' : cannot inherit from sealed class '*class2*'

A sealed class cannot act as a base class. Structs are sealed by default.

The following sample generates CS0509:

```
// CS0509.cs
namespace x
{
   sealed public class clx   // class is sealed
   {
      public int i = 0;
   }

   public class cly : clx    // CS0509
   {
      public static int Main()
      {
         return 0;
      }
   }
}
```

Compiler Error CS0513

'*function*' is abstract but it is contained in nonabstract class '*class*'

A method cannot be an abstract member of a nonabstract class.

The following sample generates CS0513:

```
// CS0513.cs
namespace x
{
   public class clx
   {
      abstract public void f();   // CS0513, abstract member of nonabstract class
   }
}
```

Compiler Error CS0514

'*constructor*' : static constructor cannot have an explicit this or base constructor call

There is no object for a static class. Therefore, the base class cannot be called. Objects must be known at compile time.

The following sample generates CS0514:

```
// CS0514.cs
namespace x
{
   public class clx
   {
      public clx(int i)
      {
      }
   }

   public class cly : clx
   {
      static cly() : base(0)  // CS0514, remove base or static
      {
      }
   }
}
```

See Also

base

Compiler Error CS0515

'*function*' : access modifiers are not allowed on static constructors

A constructor cannot have an access modifier.

The following sample generates CS0515:

```
// CS0515.cs
namespace x
{
   public class clx
   {
      public static int Main()
      {
         return 0;
      }
   }

   public class clz
   {
      public static clz()   // CS0515, remove public keyword
      {
      }
   }
}
```

Compiler Error CS0516

Constructor '*constructor*' can not call itself

A program cannot recursively call constructors.

The following sample generates CS0516:

```
// CS0516.cs
namespace x
{
   public class clx
   {
      public clx() : this()   // CS0516, delete "this()"
      {
      }

      public static void Main()
      {
      }
   }
}
```

Compiler Error CS0517

'*class*' has no base class and cannot call a base constructor

CS0517 can occur only when the .NET Framework common language runtime compiles the source code for the object class, which is the only class that has no base class.

Compiler Error CS0518

The predefined type '*type*' is not defined or imported

The main cause for this problem is that the project is not importing mscorlib.dll, which defines the entire System namespace. This can be caused by one of the following:

- The /nostdlib option from the command line compiler has been specified. The /nostdlib option prevents the import of mscorlib.dll. Use this option if you want to define or create a user-specific System namespace.
- An incorrect mscorlib.dll is referenced.
- A corrupt Visual Studio .NET or .NET Framework common language runtime installation exists.
- Residual components from an earlier installation that are incompatible with the latest installation remain.

To resolve this problem, take one of the following actions:

- Do not specify the /nostdlib option from the command line compiler.
- Make sure that the project refers to the correct mscorlib.dll.
- Reinstall the .NET Framework common language runtime (if the previous solutions do not solve the problem).

Compiler Error CS0519

'*name*' conflicts with a predefined namespace

A user-defined identifier is the same as an identifier in a predefined namespace of the common language runtime.

The following sample generates CS0519:

```
// CS0519.cs
class System   // CS0519, rename class
{
   public static int Main()
   {
      return(0);
   }
}
```

Compiler Error CS0520

'*name*' conflicts with a predefined type

One or more files needed by the compiler were not found. Reinstall the .NET Framework common language runtime.

Compiler Error CS0522

'*constructor*' : structs cannot call base class constructors

A struct cannot call a base class constructor; remove the call to the base class constructor.

The following sample generates CS0522:

```
// CS0522.cs
public class clx
{
   public clx(int i)
   {
   }

   public static void Main()
   {
   }
}

public struct cly
{
   public cly(int i):base(0)   // CS0522
   // try the following line instead
   // public cly(int i)
   {
   }
}
```

Compiler Error CS0523

Struct member '*struct2 field*' of type '*struct1*' causes a cycle in the structure layout

The definitions of two structs include recursive references. Change the struct definitions such that each does not define itself on the other.

The following sample generates CS0523:

```
// CS0523.cs
struct RecursiveLayoutStruct1
{
   public RecursiveLayoutStruct2 field;
}

struct RecursiveLayoutStruct2
{
   public RecursiveLayoutStruct1 field;   // CS0523
}

class MyClass
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0524

'*type*' : interfaces cannot declare types

An interface cannot contain a user-defined type.

The following sample generates CS0524:

```
// CS0524.cs
namespace x
{
   public interface clx
   {
      public class cly   // CS0524, delete user-defined type
      {
      }
   }
}
```

Compiler Error CS0525

Interfaces cannot contain fields

An interface can contain methods and properties but not fields.

The following sample generates CS0525:

```
// CS0525.cs
namespace x
{
   public interface clx
   {
      public int i;   // CS0525
   }
}
```

Compiler Error CS0526

Interfaces cannot contain constructors

Constructors cannot be defined for interfaces. A method is considered a constructor if it has the same name as the class and no return type.

The following sample generates CS0526:

```
// CS0526.cs
namespace x
{
   public interface clx
   {
      public clx()   // CS0526
      {
      }
   }

   public class cly
   {
      public static void Main()
      {
      }
   }
}
```

Compiler Error CS0527

'*type*' : type in interface list is not an interface

It is possible for a struct or interface to inherit from another interface but not from any other type.

The following sample generates CS0527:

```
// CS0527.cs
public struct clx : int   // CS0527, int not an interface
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0528

'*interface*' is already listed in interface list

An interface-inheritance list includes a duplicate. An interface can only be specified once in the inheritance list.

The following sample generates CS0528:

```
// CS0528.cs
namespace x
{
   public interface a
   {
   }

   public class b : a, a   // CS0528
   {
      public void Main()
      {
      }
   }
}
```

Compiler Error CS0529

Inherited interface '*interface1*' causes a cycle in the interface hierarchy of '*interface2*'

The inheritance list for an interface includes a direct or indirect reference to itself. An interface cannot inherit from itself.

The following sample generates CS0529:

```
// CS0529.cs
namespace x
{
   public interface a
   {
   }

   public interface b : a, c
   {
   }

   public interface c : b   // CS0529, b inherits from c
   {
   }
}
```

Compiler Error CS0531

'*member*' : interface members cannot have a definition

Methods that are declared in an interface must be implemented in a class that inherits from it and not in the interface itself.

The following sample generates CS0531:

```
// CS0531.cs
namespace x
{
   public interface clx
   {
      int xclx()   // CS0531, cannot define xclx
      // Try the following declaration instead:
      // int xclx();
      {
         return 0;
      }
   }

   public class cly
   {
      public static void Main()
      {
      }
   }
}
```

Compiler Error CS0533

'*derived-class member*' hides inherited abstract member '*base-class member*'

A base class method is hidden. Check the syntax of your declaration to see if it is correct.

For more information, see base.

The following sample generates CS0533:

```
// CS0533.cs
namespace x
{
   abstract public class a
   {
      abstract public void f();
   }

   abstract public class b : a
   {
      new abstract public void f();   // CS0533
      // try the following lines instead
      // override public void f()
      // {
      // }

      public static void Main()
      {
      }
   }
}
```

Compiler Error CS0534

'*function1*' does not implement inherited abstract member '*function2*'

A class is required to implement all the abstract members in the base class, unless the class is also abstract.

The following sample generates CS0534:

```
// CS0534.cs
namespace x
{
   abstract public class clx
   {
      public abstract void f();
   }

   public class cly : clx   // CS0534, no override for clx::f
   {
      // uncomment the following sample override to resolve CS0534
      // override public void f()
      // {
      // }

      public static int Main()
      {
         return 0;
      }
   }
}
```

Compiler Error CS0535

'*class*' does not implement interface member '*member*'

A class derived from an interface, but the class did not implement one or more of the interface's members. A class must implement all members of interfaces from which it derives.

The following sample generates CS0535:

```
// CS0535.cs
namespace x
{
   public interface a
   {
      void f();
   }

   public class b : a   // CS0535, a::f is not implemented
   {
      public static void Main()
      {
      }
   }
}
```

Compiler Error CS0536

'*class*' does not implement interface member '*interface member*'. '*class member*' is static, not public, or has the wrong return type

'*class*' does not implement interface member '*member1*'. '*member2*' is either static, not public, or has the wrong return type.

The compiler did not detect an interface member implementation. A declaration may be present that almost implements the interface member. Check for the following syntax errors in the declaration for the interface member:

- **public** keyword is omitted.
- Return type does not match.
- **static** keyword is present.

The following sample generates CS0536:

```
// CS0536.cs
public interface a
{
   void f();
}

public class b : a
{
   public static int f()   // CS0536
   // try the following line instead
   // public void f()
   {
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0537

The class System.Object cannot have a base class or implement an interface.

It is recommended not to declare a user-defined class called **Object** in a user-defined namespace called **System**.

The following sample generates CS0537. To resolve this error, remove the base class defined on your declaration of `System.Object` (`MarshalByRefObject`).

```
// CS0537.cs
using System;
namespace System
{
   // To resolve the error, remove the base class MarshalByRefObject.
   public class Object : MarshalByRefObject // CS0537
   {
      static void Main()
      {
      }
   }
}
```

Compiler Error CS0538

'*name*' in explicit interface declaration is not an interface

An attempt was made to explicitly declare an interface, but an interface was not specified.

The following sample generates CS0538:

```
// CS0538.cs
interface MyIFace
{
   void F();
}

public class MyClass
{
   public void G()
   {
   }
}

class C: MyIFace
{
   void MyIFace.F()
   {
   }

   void MyClass.G()   // CS0538, MyClass not an interface
   {
   }
}
```

Compiler Error CS0539

'*member*' in explicit interface declaration is not a member of interface

An attempt was made to explicitly declare an interface member that does not exist. You should either delete the declaration or change it so that it refers to a valid interface member.

The following sample generates CS0539:

```
// CS0539.cs
namespace x
{
   interface I
   {
      void m();
   }

   public class clx : I
   {
      void I.x()   // CS0539
      {
      }

      public static int Main()
      {
         return 0;
      }
   }
}
```

Compiler Error CS0540

'*interface member*' : containing class does not implement interface '*interface*'

You attempted to implement an interface member in a class that does not derive from the interface. You should either delete the implementation of the interface member or add the interface to the base-class list of the class.

The following sample generates CS0540:

```
// CS0540.cs
namespace x
{
   interface I
   {
      void m();
   }

   public class clx
   {
      void I.m()   // CS0540
      {
      }

      public static int Main()
      {
         return 0;
      }
   }
}
```

Compiler Error CS0541

'*declaration*' : explicit interface declaration can only be declared in a class or struct

An explicit interface declaration was found outside a class or struct.

The following sample generates CS0541:

```
// CS0541.cs
namespace x
{
   interface IFace
   {
      void F();
   }

   interface IFace2 : IFace
   {
      void IFace.F();   // CS0541
   }
}
```

Compiler Error CS0542

'*user-defined type*' : member names cannot be the same as their enclosing type

A name was used more than once in the same construct. This error might be caused by inadvertently putting a return type on a constructor.

The following sample generates CS0542:

```
// CS0542.cs
class F
{
   // Remove void from F() to resolve the problem.
   void F()   // CS0542, same name as the class
   {
   }
}

class MyClass
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0543

'*enumeration*' : the enumerator value is too large to fit in its type

A value that was assigned to an element in an enumeration is outside the range of the data type.

The following sample generates CS0543:

```
// CS0543.cs
namespace x
{
   enum I : byte
   {a = 255, b, c}   // CS0543
   public class clx
   {
      public static int Main()
      {
         return 0;
      }
   }
}
```

Compiler Error CS0544

'*property override*' : cannot override; '*non-property*' is not a property

An attempt was made to override a nonproperty data type as a property, which is not allowed.

The following sample generates CS0544:

```
// CS0544.cs
namespace x
{
   public class a
   {
      public int i;
   }

   public class b : a
   {
      public override int i   // CS0544
      // the following line resolves CS0544
      // public new int i
      {
         get
         {
            return 0;
         }
      }

      public static void Main()
      {
      }
   }
}
```

Compiler Error CS0545

'*function*' : cannot override because '*property*' does not have an overridable get accessor

An attempt was made to define an override for a property accessor when the base class has no such definition to override. You can resolve this error by:

- Adding a **set** accessor in the base class.
- Removing the **set** accessor from the derived class.
- Hiding the base class property by adding the new keyword in derived class's property.
- Making the base class property virtual.

The following sample generates CS0545:

```
// CS0545.cs
namespace x
{
   public class a
   {
      public virtual int i
      {
         set
         {
         }
         // uncomment this accessor to resolve CS0545
         // get
         // {
         //   return 0;
         // }
      }
   }

   public class b : a
   {
      public override int i   // CS0545
      {
         get
         {
            return 0;
         }
      }

      public static void Main()
      {
      }
   }
}
```

Property Declaration | Accessors

Compiler Error CS0546

'*accessor*' : cannot override because '*property*' does not have an overridable set accessor

An attempt to override one of the accessor methods for a property failed because the accessor cannot be overridden. You can resolve this error by:

- Adding a **set** accessor in the base class.
- Removing the **set** accessor from the derived class.
- Hiding the base class property by adding the new keyword in derived class's property.
- Making the base class property virtual.

For more information, see Property Declaration and Accessors.

The following sample generates CS0546:

```
// CS0546.cs
namespace x
{
   public class a
   {
      public virtual int i
      {
         get
         {
            return 0;
         }
         // uncomment the following accessor to resolve this CS0546
         // set
         // {
         // }
      }
   }

   public class b : a
   {
      public override int i
      {
         set   // CS0546, no set
         {
         }
      }

      public static void Main()
      {
      }
   }
}
```

Compiler Error CS0547

'*property*' : property or indexer cannot have void type

void is invalid as a return value for a property.

For more information, see Properties.

The following sample generates CS0547:

```
// CS0547.cs
public class a
{
   public void i   // CS0547
   // Try the following declaration instead:
   // public int i
   {
      get
      {
         return 0;
      }
   }
}

public class b : a
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0548

'*property*' : property or indexer must have at least one accessor

A property must have at least one accessor (get or set) method.

For more information, see Property Declaration and Accessors.

The following sample generates CS0548:

```
// CS0548.cs
public class b
{
   public int MyProp   // CS0548
   {
      // remove comments to resolve CS0548
      /*
      get
      {
         return 0;
      }
      set
      {
         return 0;
      }
      */
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0549

'*function*' is a new virtual member in sealed class '*class*'

A sealed class cannot be used as a base class, and a virtual method has to be implemented in a derived class, which is a contradiction.

The following sample generates CS0549:

```
// CS0549.cs
sealed public class MyClass
{
   virtual public void TestMethod()   // CS0549
   // to resolve, remove virtual from method or sealed from class
   {
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0550

'*accessor*' adds an accessor not found in interface member '*property*'

The implementation of a property in a derived class contains an accessor that was not specified in the base interface.

For more information, see Property Declaration and Accessors.

The following sample generates CS0550:

```
// CS0550.cs
namespace x
{
   interface ii
   {
      int i
      {
         get;
         // add the following accessor to resolve this CS0550
         // set;
      }
   }

   public class a : ii
   {
      int ii.i
      {
         get
         {
            return 0;
         }
         set // CS0550, no set in interface
         {
         }
      }

      public static void Main()
      {
      }
   }
}
```

Compiler Error CS0551

Explicit interface implementation '*implementation*' is missing accessor '*accessor*'

A class that explicitly implements an interface's property must implement all the accessors that the interface defines.

For more information, see Property Declaration and Accessors.

The following sample generates CS0551:

```
// CS0551.cs
interface ii
{
   int i
   {
      get;
      set;
   }
}

public class a : ii
{
   int ii.i   // CS0551
   {
      set
      {
      }
      // uncomment the following accessor to resolve
      /*
      get
      {
         return 0;
      }
      */
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0552

'*conversion routine*' : user defined conversion to/from interface

You cannot create a user-defined conversion to or from an interface. If you need the conversion routine, resolve this error by making the interface a class or derive a class from the interface.

The following sample generates CS0552:

```
// CS0552.cs
public interface ii
{
}

public class a
{
   // delete the routine to resolve CS0552
   public static implicit operator ii(a aa) // CS0552
   {
      return new ii();
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0553

'*conversion routine*' : user defined conversion to/from base class

User-defined conversions to values of a base class are not allowed; you do not need such an operator.

The following sample generates CS0553:

```
// CS0553.cs
namespace x
{
   public class ii
   {
   }

   public class a : ii
   {
      // delete the conversion routine to resolve CS0553
      public static implicit operator ii(a aa) // CS0553
      {
         return new ii();
      }

      public static void Main()
      {
      }
   }
}
```

Compiler Error CS0554

'*conversion routine*' : user defined conversion to/from derived class

User-defined conversions to values of a derived class are not allowed; you do not need such an operator.

See chapter 6 in the C# language specification for more information on user-defined conversions.

The following sample generates CS0554:

```
// CS0554.cs
namespace x
{
   public class ii
   {
      // delete the conversion routine to resolve CS0554
      public static implicit operator ii(a aa) // CS0554
      {
         return new ii();
      }
   }

   public class a : ii
   {
      public static void Main()
      {
      }
   }
}
```

Compiler Error CS0555

User-defined operator cannot take an object of the enclosing type and convert to an object of the enclosing type

User-defined conversions to values of the enclosing class are not allowed; you do not need such an operator.

The fo3llowing sample generates CS0555:

```
// CS0555.cs
public class MyClass
{
   // delete the following operator to resolve this CS0555
   public static implicit operator MyClass(MyClass aa)   // CS0555
   {
      return new MyClass();
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0556

User-defined conversion must convert to or from the enclosing type

A user-defined conversion routine must convert to or from the class that contains the routine.

The following sample generates CS0556:

```
// CS0556.cs
namespace x
{
   public class ii
   {
      public class iii
      {
         public static implicit operator int(byte aa)   // CS0556
         // try the following line instead
         // public static implicit operator int(iii aa)
         {
            return 0;
         }
      }

      public static void Main()
      {
      }
   }
}
```

Compiler Error CS0557

Duplicate user-defined conversion in class '*class*'

Duplicate conversion routines are not allowed in a class.

The following sample generates CS0557:

```
// CS0557.cs
namespace x
{
   public class ii
   {
      public class iii
      {
         public static implicit operator int(iii aa)
         {
            return 0;
         }

         public static explicit operator int(iii aa)   // CS0557, delete duplicate
         {
            return 0;
         }
      }

      public static void Main()
      {
      }
   }
}
```

Compiler Error CS0558

User-defined operator '*operator*' must be declared static and public

Both the **static** and **public** access modifiers must be specified on user-defined operators.

The following sample generates CS0558:

```
// CS0558.cs
namespace x
{
   public class ii
   {
      public class iii
      {
         static implicit operator int(iii aa)   // CS0558, add public
         {
            return 0;
         }
      }

      public static void Main()
      {
      }
   }
}
```

Compiler Error CS0559

The parameter and return type for ++ or — operator must be the containing type

The method declaration for an operator overload must follow certain guidelines.

The following sample generates CS0559:

```
// CS0559.cs
public class iii
{
   public static implicit operator int(iii x)
   {
      return 0;
   }

   public static implicit operator iii(int x)
   {
      return null;
   }

   public static int operator ++(int aa)   // CS0559
   // try the following line instead
   // public static iii operator ++(iii aa)
   {
      return (iii)0;
   }

   public static void Main()
   {
   }
}
```

Compiler Error CS0560

Accessor '*accessor1*' : cannot override '*accessor2*' because it is hidden by '*function*'

A property definition is hidden in an indirect base class.

For more information, see Property Declaration and Accessors.

The following sample generates CS0560:

```
// CS0560.cs
namespace NC
{
   class B
   {
      virtual public int Prop
      {
         get
         {
            return 0;
         }
         set
         {
         }
      }
   }

   abstract class D : B
   {
      public new int set_Prop(int i)
      {
         return 0;
      }

      // to resolve this CS0560, delete the set_Prop method and
      // uncomment the definition of Prop
      /*
      public override int Prop
      {
         set
         {
            return;
         }
         get
         {
            return 0;
         }
      }
      */
   }

   class DD : D
   {
      // override blocked by non-accessors
      public override int Prop
      {
         get
         {
            return 0;
         }
         set   // CS0560
         {
            return;
         }
      }

      public static void Main()
```

```
        {
        }
    }
}
```

Compiler Error CS0561

'*function*' : cannot override '*accessor*' because it is a special compiler-generated method

A property declaration created a hidden virtual method (accessor) named **Get*property_name***. That accessor name conflicts with a method name. You can only override this accessor method through a property override not a method override.

The following sample generates CS0561:

```
// CS0561.cs
class B
{
   public virtual int Prop
   {
      get
      {
         return 0;
      }
   }
}

class C : B
{
   public override int get_Prop()   // CS0561
   {
      return 0;
   }

   /* Try the following instead:
   public override int Prop
   {
      get
      {
         return 0;
      }
   }
   */

   public static void Main()
   {
   }
}
```

Compiler Error CS0562

The parameter of a unary operator must be the containing type

The method declaration for an operator overload must follow certain guidelines. For more information, see Overloadable Operators.

The following sample generates CS0562:

```
// CS0562.cs
namespace x
{
   public class iii
   {
      public static implicit operator int(iii x)
      {
         return 0;
      }

      public static implicit operator iii(int x)
      {
         return null;
      }

      public static iii operator +(int aa)   // CS0562
      // try the following line instead
      // public static iii operator +(iii aa)
      {
         return (iii)0;
      }

      public static void Main()
      {
      }
   }
}
```

Operator Overloading Tutorial

Compiler Error CS0563

One of the parameters of a binary operator must be the containing type

The method declaration for an operator overload must follow certain guidelines. For more information, see Overloadable Operators.

The following sample generates CS0563:

```
// CS0563.cs
public class iii
{
   public static implicit operator int(iii x)
   {
      return 0;
   }
   public static implicit operator iii(int x)
   {
      return null;
   }
   public static int operator +(int aa, int bb)   // CS0563
   // Use the following line instead:
   // public static int operator +(int aa, iii bb)
   {
      return 0;
   }
   public static void Main()
   {
   }
}
```

Operator Overloading Tutorial

Compiler Error CS0564

Overloaded shift operator must have the type of the first operand be the containing type, and the type of the second operand must be int.

You attempted to overload a shift operator (<< or >>) with incorrectly typed operands. The first operand must be the type and the second operand must be of the type **int**.

The following sample generates CS0564:

```
// CS0564.cs
using System;
class C
{
   public static int operator << (C c1, C c2) // CS0564
// To correct, change second operand to int, like so:
// public static int operator << (C c1, int c2)
   {
      return 0;
   }
   static void Main()
   {
   }
}
```

Compiler Error CS0567

Interfaces cannot contain operators

Operators are not permitted in interface definitions.

The following sample generates CS0567:

```
// CS0567.cs
interface IA
{
   int operator +(int aa, int bb);   // CS0567
}

class Sample
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0568

Structs cannot contain explicit parameterless constructors

Each struct already has a default constructor that initializes the object to zero. Therefore, the constructors that you can create for a struct must take one or more parameters.

The following sample generates CS0568:

```
// CS0568.cs
public struct ClassY
{
   public int field1;
   public ClassY(){}   // CS0568, cannot have no param constructor
   // Try following instead:
   // public ClassY(int i)
   // {
   //    field1 = i;
   // }
}

public class ClassX
{
   public static void Main()
   {
   }
}
```

Compiler Error CS0569
